Penicillin does not influence the growth of organisms in areas which have little or no blood-supply. The cases recorded below show that penicillin-sensitive organisms can thrive in a dead tooth pulp, or even in an apical dental granuloma, while a patient is undergoing treatment with massive doses of systemic penicillin. The importance of this in diseases such as bacterial endocarditis and metastatic osteomyelitis cannot be too strongly emphasised. It seems in many such cases that relapse after penicillin therapy is due to "a bacterial leak" from an infected tooth, or possibly tonsil, after the penicillin has been discontinued.

CASE 1.—*Osteomyelitis of rib.* Blood-culture gave *Staph. aureus.* Penicillin 2,700,000 units was given in twenty seven days. Then two infected incisor teeth were removed. Cultures from the pulp of one of these teeth yielded a fully penicillin-sensitive *Staph. aureus.*

CASE 2.—*Septic arthritis of both sacro-iliac joints, with multiple sinus formation.* Three years' history. Cultures yielded a staphylococcus and a hæmolytic streptococcus. The patient was given penicillin 48,000,000 units, in three courses over a period of twelve months. A dead upper molar was extracted during the last week of the third course. Organisms cultured from the pulp yielded a staphylococcus and a *Strep. viridans*, both of them penicillin-sensitive. A week later the sinuses were dry. Six months later they are still dry and the patient is back at work.

CASE 3.—*Bacterial endocarditis.* Penicillin 25,000,000 units was given in twenty-five days. Then an upper premolar was extracted. Cultures from the centre of an apical granuloma yielded a scanty growth of *Strep. viridans*, fully penicillin-sensitive.

The penicillin was continued for a further seven days, and the patient was discharged from hospital shortly afterwards. Four months later she is awaiting admission to hospital for further dental extractions, for cosmetic reasons, under a penicillin "umbrella."

CASE 4.—*Dental abscess*, which had been treated with penicillin 100,000 units a day for three days. When I first saw the patient on extraction, cultures of the pus were sterile, but those from the tooth pulp yielded *Strep. viridans* and a few *Staph. albus* and diphtheroids, all fully penicillin-sensitive. The diphtheroids were probably contaminants.

Numbers of "sterile" reports were received on cultures from teeth roots in similar cases. Not a few of these were probably due to excessive zeal in the flaming of the outer surface of granulomata before dividing them for culturing from their centre. The proportion of sterile findings and positive ones was about equally divided.

I wish to thank Dr. E. T. Baker-Bates, Dr. C. Astley Clarke, and Mr. J. P. Heron, who have given me every assistance with their cases; and Dr. W. K. Taylor for his invaluable bacteriological work.

Liverpool. JOHN W. HALLAM.

TUBOCURARINE IN TETANUS

SIR,—The use of curare in the treatment of tetanus was suggested nearly seventy years ago, and in 1934 and 1935 Cole[1] reported cases in which it was employed with some success. The difficulty encountered at that time was the lack of standardised preparations, and therefore the establishment of a suitable dose was impossible. Further, there is only a narrow margin between the dose which will be effective in controlling the spasms and that which will affect seriously the respiratory muscles.

The introduction of tubocurarine and the wide experience gained in its use as an adjuvant to anæsthesia prompted its administration in a recent case. Although this case ultimately proved fatal, the injections of tubocurarine produced symptomatic improvement and were much appreciated by the patient, who repeatedly asked for them when the next dose was due.

The opportunities of treating tetanus in London are rare, and the purpose of this note is to indicate the dose of tubocurarine which was found satisfactory. The patient was a woman, aged 38, having an estimated body-weight of 7 st. Tubocurarine chloride 7·5 mg. by intramuscular injection every two hours produced maximum muscular relaxation without having any apparent effect on the respiratory mechanism.

Other features of interest in this case were that the patient had cut her finger in a hop-field one week before admission to hospital. The first symptoms, observed four days after the cut, were nasal regurgitation of fluid and difficulty in swallowing when having lunch. These symptoms were predominant throughout the duration of the condition, and the accumulation of saliva and mucous secretion in the mouth and pharynx was very troublesome. On the other hand, although there was considerable muscular rigidity, the spasms were relatively mild and infrequent and caused little evidence of exhaustion.

During the eleven days the patient survived in hospital it was impossible to administer any fluid or nourishment by mouth, but in spite of this there was no dehydration. The general condition was well maintained by the continuous intravenous infusion (great saphenous vein above the internal malleolus) of 5% glucose in $^{1}/_{5}$th normal saline, 2500 ml. every 24 hours. Heparin 10 mg. was added to each 1000 ml. Large doses of tetanus antitoxin (total 573,000 units) and penicillin (total 1,710,000 units) were administered in the drip infusion. As a sedative, paraldehyde 6 ml. every four hours was given by intramuscular injection.

The fatal termination of this case was attributed to the fact that early bulbar symptoms developed before treatment with antitoxin could be instituted, and in spite of the control of spasms by paraldehyde and tubocurarine.

Mile End Hospital, London, E.1. W. GORDON SEARS.

THE HEALTH OF AUTHORS

SIR,—Mr. Harold Nicolson's lecture before the Royal College of Physicians, published in your Nov. 15 issue, was delightful reading—such indeed as one expects from Mr. Nicolson. Its appearance in your journal, too, is a welcome relief from considerations of erythroblastosis fœtalis et al.

In his cogent and lucid exposition of the Nature of Inspiration, Mr. Nicolson defines inspiration as "a sudden flash or fusion between sense and fantasy, between reason and imagination," but he is careful to explain and to illustrate that it may vary in intensity and in degree, producing a physical revolt or reaction on the more acutely sensitive temperaments. And such a temperament is, as he says, most often found in the favoured, or afflicted, of the Muses.

Now Mr. Nicolson confines himself, and rightly, to his own chosen sphere—the art of letters. But so far as his lecture might be taken to imply by omission that the divine afflatus and oneiromancy are the peculiar prerogatives of poets and writers only, I would suggest that precisely similar phenomena have been experienced by mathematicians and scientists *pur sang*—and not without comparable stupendous flowering of result.

Two years ago—up to which time I had myself so wrong a notion—I came across Father Henry Gill's (S.J.) book *Fact and Fiction in Modern Science.* His very first chapter is headed Flashes of Genius, and two mathematicians of international repute, Sir William Rowan Hamilton and Henri Poincaré, are adduced to speak in the matter for themselves. While Father Gill is content to cite two examplars of inspiration, and dream, whose best work was due to such external influence, it may be presumed that they were no exceptions to what after all may be an inherent susceptibility in what some call "the human organism."

It is a commonplace that the practice of medicine is an art rather than a science; but a gathering of our profession may be said to approximate more nearly to a convention of scientists than a galaxy prostrate at the feet of the Muse. It is as scientists that we may find a little reflection salutary, even if Mr. Nicolson refrained from asking whether we needed an apologia ourselves. At any rate with him we can be that much more on the side of the angels; and free to some extent at least from Sinclair Lewis's gibe when he called us "the men of measured merriment."

Finally, in renewing my thanks to Mr. Nicolson for a most enlivening and invigorating paper, may I take leave to ask him why he omitted mention of Christopher Smart and his *Song to David*? Sublime poetry and stark lunacy here go merrily hand in hand for dozens and dozens of stanzas. Selene and Euterpe may it seems bed together in silver peace. Perhaps someone else will tell us whether Urania sleeps alone? Or her fledglings the psychiatrist and the psychologist?

Cheslyn Hay, Staffordshire. L. Dillon Malone.

TREATMENT OF BOILS

Sir,—With reference to the letters by Dr. Valentine (Nov. 15) and Dr. Foot (Nov. 1), I wish to say that I have been using systemic penicillin for boils and carbuncles for over nine months.

During the last six weeks alone I have dealt with seventeen patients suffering from boils and carbuncles situated in various parts of the body. The treatment consisted of one injection into the vastus lateralis muscle of 10 ml. oil-wax suspension of penicillin calcium, 125,000 units per ml. They all invariably noticed subsidence of pain and swelling, commencing between four and six hours after the injection, and all were discharged fit for work within 7 days. The reactions were pain radiating down the limb during the injection, followed sometimes by a severe fainting bout. There was stiffness of the injected limb, which lasted up to a fortnight. On the 8th day, in two cases, a gross swelling of the thigh and an itchy erythematous rash developed, which subsided in 3–4 days without any treatment. A few months ago I had two cases of urticarial reaction spreading over the whole body, following penicillin injection; one case I described in The Lancet of July 5.

One word about local treatment—none. A piece of dry lint or gauze was placed on the discharging area, if any. This was replaced daily if the discharge was profuse. If there was a large sloughing area, a few grains of crystals of urea were sprinkled on daily.

Many of these patients had had previous attacks of boils and carbuncles, usually lasting for weeks, or even months, and these patients were all impressed by the dramatic improvement following the penicillin injection, and also by the absence of local treatment.

During the last six months I have noticed an enormous increase of boils and carbuncles. Next to the common cold, furunculosis has been the most prevalent disease amongst the patients attending my surgery, and I wonder whether other practitioners have had an experience similar to mine.

Sheffield. I. Gottlieb.

TYPHOID CARRIERS TREATED WITH PENICILLIN AND SULPHATHIAZOLE

Sir,—We have previously reported observations on two typhoid carriers treated with penicillin and sulphathiazole.[1] A further report is now presented to cover the first year after treatment.

Frequent specimens of early-morning urine and specimens of almost all stools passed were cultured for *Bact. typhosum* on Wilson and Blair's medium, and on desoxycholate agar plates inoculated direct and after incubating a portion of each specimen in selenite F. Many specimens of fæces and urine were also inoculated direct on MacConkey plates. Some 2500 culture plates were examined in each case. *Bact. typhosum* has not been isolated from any specimen. Agglutinations of sera against *Bact. typhosum* H, O, and Vi have also been carried out in both cases.

Case 1.—This patient died on Nov. 1, 1946, from intercurrent pneumonia followed by lung abscess. Post mortem, there was no evidence in the organs of continuing typhoid infection. Bacteriological cultures from gut, biliary and urinary tracts, spleen, and lungs did not yield *Bact. typhosum.* From the first negative cultures during the course of treatment to death 198 days later, 534 samples from 137 stools and 27 samples of 136 urines did not yield the organism.

Results of serum agglutinations may be summarised follows: *Bact. typhosum* H, initial titre 1/125 declined to 1/4 on Sept. 27, 1946; *Bact. typhosum* O, initial titre 1/50 rose to maximum of 1/320 and then fell to 1/160 on Sept. 27, 1946 *Bact. typhosum* Vi was further reduced from the lowest valu previously reported (+ in 1/5 dilution) to a trace (±) 1/5 dilution on Sept. 27, 1946.

Case 2.—This patient is alive and well, her physical con dition being substantially better than before her treatmen During the year following the first negative cultures in th course of treatment bacteriological examination of 491 sampl from 146 stools and of 314 samples from 157 urines did n yield *Bact. typhosum.*

Results of serum agglutinations: *Bact. typhosum* initial titre 1/500 fell to 1/80 on June 12, 1947; *Bact. typhosu* O, initial titre 1/50 rose to 1/160 and then declined to 1/20 June 12, 1947; *Bact. typhosum* Vi, titre has remained roughl as previously reported, + being found in 1/5 dilution June 12, 1947.

These two patients, both of whom before treatme freely excreted *Bact. typhosum* in their fæces, are regarde as having been cured of the typhoid carrier state, much reliance being placed on the change in agglutinatio titres as on the negative bacteriological findings. Th increase in *Bact. typhosum* O agglutination titre followin the decrease in Vi titre observed in these cases h also been observed by one of us (W. W. K.) in one oth typhoid carrier successfully treated with penicilli sulphathiazole. It is hoped to report and discuss the and other agglutination results in detail on some futu occasion.

We wish to thank Dr. L. C. Cook, medical superintende of Bexley Hospital, for his continued interest; and the sta responsible for nursing the patients and our technical sta in particular Mr. L. W. Tuttle and Mr. C. R. Wright, for the painstaking coöperation.

C. H. Comerford

DEPERSONALISATION SYNDROME

Sir,—I read with interest and concern Dr. Shorvon' article in your issue of Nov. 15.

The cases he quotes in favour of prefrontal leucotom seem to me not at all convincing. The price his patient have paid for their symptomatic improvement seems be the loss of an essential human quality. For exampl of case 4, a woman of 26, he reports: "Six weeks aft the operation her father died suddenly, and she took in an off-hand manner and was 'surprised.' Her attitud to her brother had completely altered, and she gets o well with him. 'I don't worry about him. I don' worry about anything any more.'"

As regards this brother she had experienced a dee unresolved conflict, for which she received "eight electr convulsion shocks and a course of modified insulin an narcosis without success." Later she "derived no benef from psychotherapy, vasodilators, vitamins, amphet amine, epanutin, and narco-analysis."

Psychotherapy is often quoted in similar vein "psychotherapy and a course of deep insulin had littl effect."

Psychotherapy is not yet another method of treatment; it is an essential orientation. Depersonalisatio is a defensive reaction against an unbearable conflict— problems of the patient's life which he is unable to face The question is whether we are willing and able to fac them with him, or not. This would remain *no less* tru even if we know the pathology of the depersonalisatio syndrome on the somatic level, which we do not. W cannot talk about this condition as attacks whic descend upon the patient—e.g., "he felt ill and weak afte the onset of unreality," and "the 2 who had recovered immediately had had previous clear-cut attacks o unreality," and so on.

It is true that these cases are difficult to treat successfully, and that even for prolonged psycho-analytic treatment the prognosis is not too good. The psychoanalysis of such cases is a matter for specially skilled and qualified analysts and requires daily sessions over a period of three years; and it could therefore in any case be obtained only by a very few. If the necessary skill for analysis is present only in a few, this must be even more true for the general run of psychiatrists. Abbreviated treatment is even more difficult and demands even more experience, and it is still too time-consuming under our present conditions. My sympathy goes out to Dr. Shorvon and all harassed colleagues in their race against time and the overwhelming claims of this type of patient, particularly if they appear in numbers. It may well be that such emergency treatment as he reports is inevitable under present conditions. Moreover, it might be the only practicable measure for selected cases with a very unfavourable prognosis.

---

[1] Comerford, C. H., Richmond, H., Kay, W. W. *Lancet*, 1946, ii, 343.

* Dr. Richmond has died since this communication was sent to us.—Ed. L.

But this does not alter the fact that these patients are often exceedingly good material for psychological approach, if they are approachable at all; and all those I have seen have proved to be so. Dr. Shorvon's own beautiful quotations bear this out, but one can well believe him that "they have the utmost difficulty in describing their symptoms and in being understood."

In view of all this it seems to me of particular interest to mention that I have seen several such cases in group analysis, and all of them did exceedingly well, and that on genuine grounds. They regained their feelings, developed constructive insight, were able to see and face their problems, and showed self-progressive powers of integration. In short, they left treatment in a better state than they would have been likely to achieve if they had never developed "attacks of unreality." In at least three cases the depersonalisation syndrome was the outstanding feature, but it should be mentioned that they were all above average intelligence. Two of them stayed with their respective groups for under a year and had only one individual session per week in addition to the group session. One such case, diagnosed as "essential" or "primary" depersonalisation, attends at the present moment at St. Bartholomew's Hospital a weekly group analytic session—together with seven other patients—and she progresses very well indeed, without any supplementary individual session.

These results are due in no small degree to the superior power of the group situation, if it can be harnessed to the service of therapy.

London, W.1. S. H. FOULKES.

STREPTOMYCIN IN INFLUENZAL MENINGITIS

SIR,—Dr. Cormac's letter in your issue of Nov. 8 necessitates a reply from me.

In a disease such as influenzal meningitis in infancy, which had a mortality of almost 100% before specific therapy was introduced, an obvious clinical response to massive doses of penicillin in 3 cases, despite the bacteriological reports that the organisms were insensitive to penicillin, was suggestive that this "insensitivity" was merely relative to the concentration of penicillin used in the test. This was, in fact, confirmed by Dr. E. N. Allott in our last 2 cases, when he found the bacteria to be markedly sensitive to higher concentrations of penicillin; but the strains varied widely in their sensitivity. The clinical study of 4 cases of influenzal meningitis was therefore sufficient to prove that this disease will respond to massive doses of penicillin and that the view originally held, that *H. influenzæ* was insensitive to penicillin, was incorrect. Later, when reviewing the literature, I came across the paper by Gordon and Zinnemann,[1] who had made a similar observation in their laboratory on examination of eighteen different strains of *H. influenzæ*. They found all these to be inhibited by high concentrations of penicillin, but in very varying degree. Our clinical experience and independent conclusion was thus entirely in keeping with their bacteriological findings.

I therefore maintain that the use of streptomycin in the treatment of influenzal meningitis does not appear to be justified at present, owing to its limited supply, until penicillin in massive dosage has at first been tried and found ineffective. It seems to me to be more reasonable to confine its use at present to the treatment of as many cases as possible of the hæmatogenous forms of tuberculosis and for a clinical trial against infections due to other sulphonamide-resistant and penicillin-resistant bacteria.

St. Alfege's Hospital, London, S.E.10. B. GOTTLIEB.

HORMONE TREATMENT BY IMPLANTING PELLETS

SIR,—In reviewing at the moment my cases of Simmonds's disease for detailed reporting, I am reminded that the general statement I made in my letter published on Oct. 11 applied to the more usual use of testosterone in eunuchoid cases, and I should be obliged if you would permit me to add that testosterone tablet implantations in Simmonds's disease, in women, are less well tolerated than in eunuchoidism, and not infrequently are extruded from the site of implantation.

It would appear, therefore, that not only the physicochemical properties of the implanted hormone but also the reactivity of the tissues are important; and that this reactivity is, at least to some extent, dependent upon the particular endocrinopathy.

London, W.1. S. L. SIMPSON.

RENAL CIRCULATION

SIR,—In their letter (Nov. 22) Dr. Trueta and Dr. Barclay state that at the meeting of the Physiological Society on June 15, 1946, they—

> "exhibited photographs and photomicrographs of kidneys that 'incline us to believe that the by-passing is effected, at least in part, via the vasa recta.' We demonstrated vasa recta with their loops *arising from glomeruli at the base of the cortex and at that time, called them basal glomeruli.*"

It is most unfortunate that this last sentence, especially that part which I have italicised, or its equivalent, was omitted first from their report in the proceedings of the Physiological Society (*J. Physiol.* 1946, 105, 27) and secondly from their preliminary communication in THE LANCET (1946, ii, 237). Permit me to quote the pertinent paragraphs from these communications. In the first-mentioned they concluded:

> "Evidence . . . shows that short-circuiting of various degree can occur in the kidney and . . . that it can be accompanied by functional cortical ischæmia. This suggests a much greater degree of short-circuiting than could be accounted for by anatomical evidence so far published, and our investigations, though they are not yet complete, incline us to believe that the by-passing is effected, at least in part, via the vasa recta."

In the second they wrote:

> "The above observations show that as a result of appropriate nerve-stimulation the blood may be diverted wholly or partly from the cortex and short-circuited through medullary (especially subcortical) blood-channels. The large potential capacity of these by-passing channels enables them to transmit the whole of the renal blood inflow whenever the supply to the cortex is diverted and the latter thereby rendered ischæmic.
>
> "To locate the by-passing channels histologically, particulate material was injected in place of dyes, and was found to fill vasa recta and their loops, as well as a subcortical plexus of vessels (also of very much more than capillary calibre) suggesting that these two sets of vessels were the anatomical channels involved. These histological studies are being continued."

In brief, at first they considered the by-passing to be "effected, at least in part, via the vasa recta," and later they demonstrated "vasa recta and their loops, as well as a subcortical plexus of vessels . . . suggesting that these two sets of vessels were the anatomical channels involved."

There are two kinds of vasa recta in the kidney—vasa recta vera and vasa recta spuria. There is no indication which was thought to be concerned. Furthermore, in a matter affecting a short-circuit in the circulation in the kidney, a thing so fundamental as the glomerular or non-glomerular aspect of the short-circuit is omitted; indeed neither the word "glomerulus" nor "glomeruli" appear in either communication. However it was stated that the investigations were not yet completed and that the histological studies were being continued.

---

[1] Gordon, M., Zinnemann, K. *Brit. med. J.* 1945, ii, 795.

Such then was the declared stage when my letter appeared (*Lancet*, 1946, ii, 436) in which, following argument and examples, anatomical, physiological, and pathological, and finally mathematical, I stated:

> "... from a consideration of the hæmodynamics of the renal circulation in the rabbit, it is possible to suggest that the degree and character of the altered renal circulation, as outlined by Dr. Trueta and his colleagues, and the 'redistribution of blood-flow within the kidney' discussed by Professor Maegraith (p. 213), could be maintained by a circulation via the deep (subcortical or juxtamedullary) glomeruli only, the cortex being relatively avascular, by vasoconstriction of the peripheral arterial vessels in response to afferent (sciatic or other) stimuli."

My experimental work was first reported to, and demonstrated at, a meeting of the Pathological Society of Great Britain and Ireland held in July, 1941. This was the year in which I described the *juxtamedullary glomeruli*, as I mentioned at the recent meeting of the Royal Society of Medicine.

North Middlesex County Hospital,
London, N.18.

J. F. HEGGIE.

SPIRILLUM MINUS TREATMENT OF G.P.I.

SIR,—The records of the experiment in therapy described here were lost during the Malayan campaign. Dr. W. R. Logan, who investigated the cases clinically and made elaborate records of the progress of the patients, lost his life at the Alexandra Hospital when it was stormed by Japanese troops a few days before the surrender of Singapore. His death was a serious loss to psychiatry in the Far East and to many friends who appreciated his ability and personal charm.

General paralysis of the insane (G.P.I.) is by no means rare in the Federated Malay States. In 1940–41, when this investigation was carried out, we identified more than 100 cases by clinical and serological criteria in a population of rather more than 3000 patients at the Central Mental Hospital. The patients included Chinese, Malays, and Indians, the first-named predominating. Syphilis is prevalent among the Chinese and Indians in the cities and towns, but relatively uncommon among the riverine Malays, who are however subject to yaws.

The treatment of G.P.I. in Malaya presented two special difficulties. First, patients seldom reached the Central Mental Hospital until they were in an advanced state of physical and mental deterioration. Most of them had received no antisyphilitic therapy since they were first infected. About half the cases in this experiment were beyond treatment and could only be regarded as forlorn hopes. Only a few patients, who had held clerical appointments in the government service or had been in some other position that brought them to hospital relatively early in the course of their complaint, could be considered in any way promising material. The second difficulty was that most of the patients had had malaria, wherefore the possibility of successful malaria therapy was remote. Further, in the presence of anopheline mosquitoes capable of transmitting malaria there was the risk that other patients might be accidentally infected. Since we had no apparatus for inducing hyperpyrexia, we had to try some other method.

Sporadic cases of rat-bite fever (sodoku) are not uncommon in Malaya. During the latter part of 1940 one of us (J. O. P.) saw 2 cases. In the first case, though cultural methods failed, the infection was easily established in guineapigs. Two experimental infections made with guineapig blood did not give rise to an adequate fever, and this strain, though maintained for a while, was not used again. In the second case the infection was again established in guineapigs. Since this strain appeared to be more virulent it was used for the remainder of the experimental infections of cases of G.P.I.

No difficulty was encountered in maintaining the strains by passage in guineapigs. The animals were inoculated by the intraperitoneal route and about a week later became feverish, their eyes bloodshot, and their appetites poor. For one or two months their condition would slowly deteriorate, with loss of weight and an increasingly mangy appearance. They were then killed, and blood or liver emulsion from them was introduced into other animals. In this way an ample supply of blood for the inoculation of patients was always available.

Spirillum minus was repeatedly identified in the blood and livers of the guineapigs, both in wet and in stained preparations. The morphology of the two strains appeared to be identical, the spirilla varying greatly in length, number of spirals, and number of flagella.

Forty experimental human infections had been completed when war ended the investigation. In the first 6 cases guineapig blood was introduced into the skin of the arm. In 2 of these cases the development of fever was accompanied by serious ulceration spreading from the point of inoculation. In one case the ulcer spread until its diameter was about 6 in. and it had involved the underlying muscle to such a degree that the humerus was almost exposed. The healing that followed treatment with neoarsphenamine was remarkable, the scarring being far less than one could have believed possible. This method of introducing the infection was abandoned, and in the remaining cases a few drops of guineapig blood or liver emulsion diluted ten times with saline were injected into the antecubital vein with a fine needle, every effort being made not to allow any of the infected fluid to contaminate the skin or subcutaneous tissue. In a few cases a small ulcer developed at the site of inoculation, but in the remainder there was little or no local reaction.

The incubation period was seven or eight days in nearly all cases. A few patients had premonitory symptoms on the fifth or sixth day, and in a few others the onset of symptoms was delayed by a few days. Only in two or three cases was there a failure to infect at the first attempt, and in none of these was a second inoculation unsuccessful. The fever produced was satisfactory in a high proportion of cases, reaching a peak of 104°F, usually on the third evening after the onset of symptoms. In 2 cases a maximal temperature of 106°F was achieved. The fever was accompanied by considerable prostration, and the condition of some of the patients at this time was rather alarming because of their collapsed state and rapid and almost imperceptible pulse; yet no patient died during the febrile phase, and the recovery in their condition as the fever passed was remarkable. The temperature never remained high for more than 72 hours.

Most of the patients showed the typical dusky maculo-papular rash during the fever, and in a few instances a hot bath revived the rash a day or two after it had apparently cleared. In those cases in which a leucocyte-count was made during fever there was a well-marked neutrophil leucocytosis and often an increased proportion of eosinophils. The second bout of fever usually occurred about the sixth day after the first and was usually as severe as the first and in a few instances more severe. In most cases the third cycle showed a falling off, and it was our usual practice to terminate the infection the day before the fourth or fifth rise of temperature was expected. In some cases one injection of neoarsphenamine 0·5 g. was insufficient, and in a week or so the temperature rose again. Three injections of 0·5 g. at intervals of five days never failed to terminate the infection.

Albuminuria was usually present during the pyrexial period, often with casts, and it tended to persist, though diminishing, even after the fever had been terminated. Four patients died in uræmia, and the tendency to a progressive nephritis was a serious drawback to this method of fever therapy. In view of the fact that *Treponema pallidum*, *Sp. minus*, and arsenic all have a predilection for inflicting renal damage it is perhaps surprising that there were not more deaths from uræmia. It is most unfortunate that the organs removed post mortem from these cases and preserved were never studied.

In about 6 cases spectacular improvement in the mental condition was judged by Dr. Logan to have taken place. One previously intelligent Malay, who had held a position of some responsibility in the government service and, though in an early stage of dementia at the time of treatment, was in good physical condition, apparently recovered completely; but his subsequent history is unknown. Some other patients also showed evidence of improvement. For about half the patients, many too advanced to be a fair test of the treatment, the only result was a further decline in their physical condition.

J. ORDE POYNTON.

Adelaide.

THE CHRONIC PARETIC

SIR,—I was interested in Dr. Kirman's article last week as I had made a similar investigation on a small series of 15 cases, the result of which was summarised in the *Annual Report of the Board of Control* (1933, part 2, p. 71). I then found that the minimum interval after malaria therapy for the establishment of negative reactions in the cerebrospinal fluid (C.S.F.) was eleven months. The Meinicke clarification reaction appeared to be the most sensitive and remained positive in the blood and C.S.F., but I have no doubt this too became negative after the lapse of more years. It is interesting to note that in Dr. Kirman's series nearly 50% showed negative blood Wassermann reactions. In my series they all became negative, but of course the number was too small for accurate statistical conclusions.

The important point to stress—I do not think this is too well known by general practitioners—is that the attainment of negative reactions by no means guarantees a cure.

Park Prewett Mental Hospital,
Basingstoke.

I. ATKIN
Medical Superintendent.

TEACHING APPOINTMENTS

SIR,—Possibly I am attaching too much importance to the unsigned letter on the above subject which appeared last week; but the accusation that medical schools have appointed unsuitable persons to professorships of medicine is a serious one which appears to call for an answer, however irresponsible the accuser.

"M.R.C.P." tells us that he knows "from personal experience and the opinions of interested friends" that the teaching of medicine in many schools is of poor quality, and he apparently attributes this in large part to the appointment of "research-workers" to chairs of medicine. I cannot claim personal knowledge of all medical schools in the country; but I greatly doubt the validity of the writer's adjective, "many." And I can say, from personal acquaintance with numerous teachers in several schools and from knowledge of their students' opinion of them, that it is to those very teachers against whom "M.R.C.P." directs his criticism that I myself should turn to find examples of most of those qualities which he rightly implies to be desirable in those responsible for medical teaching—"knowledge of general medicine, clinical experience, ability to lecture, enthusiasm, and flare [sic] for teaching." "M.R.C.P." tells us that research-workers are often bad clinicians and poor teachers. That may be; but it is not from among this group, however valuable their contribution to society, that medical schools make their appointments to chairs of medicine.

The University, Sheffield.

J. G. McCRIE
Dean, Faculty of Medicine.

SIR,—Your anonymous correspondent "M.R.C.P." has done well in directing public attention to the disastrous consequences of appointing teachers who cannot teach. Yet in the name of progress this policy has been adopted by our universities. In so doing, they have abandoned the first principles of education as known to western civilisation. To make this clear beyond a peradventure, I would quote a profound thinker and the *greatest prose writer of the last century*, Cardinal Newman[1]:

> "... when the Church founds a University, she is not cherishing *talent, genius, or knowledge, for their own sake*, but for the sake of her children, with a view to their spiritual welfare and their religious influence and usefulness, with the object of training them to fill their respective posts in life better, and of making them more intelligent, capable, active members of society.
>
> "Nor can it justly be said that in thus acting she sacrifices Science, and, under a pretext of fulfilling the duties of her mission, perverts a University to ends not its own, as soon as it is taken into account that there are other institutions far more suited to act as instruments of stimulating philosophical enquiry, and extending the boundaries of our knowledge, than a University. Such, for instance, are the literary and scientific 'Academies' which are so celebrated in Italy and France, and which have frequently been connected with Universities, as committees, or, as it were, congregations or delegacies subordinate to them. . . . The nature of the case and the history of philosophy combine to recommend to us this division of intellectual labour between Academies and Universities. To discover and to teach are distinct functions; they are also distinct gifts, and are not commonly found united in the same person."

After Newman's stately prose I have nothing to add, save to answer in advance him who shall say: "You can't put the clock back." If your clock is wrong you put it right; and if you are approaching the brink of a precipice you go back—or perish.

London, W.8.

HALLIDAY SUTHERLAND.

FLARE-UP IN THE GLASS HOUSE?

SIR,—The feast of jugged hair (Nov. 22, p. 773) was suitably illumined by the weird glow of the flare in the next letter with its "flare for teaching." Spelling apart, we do not speak of "flair," but only of "*a* flair," and it means a keen nose for scenting the not very obvious; it does not mean a gift in general.

Prof. Pomfret Kilner himself is not quite blameless, for he writes "inapt": this is rightly condemned as a bastard blend of "inept" and "unapt."

AQUARIUS.

HANDKERCHIEFS IMPREGNATED WITH DISINFECTANT

SIR,—The possibilities of treating textiles with disinfectants are of considerable general interest.

We have recently had an opportunity to try out a relatively simple method of impregnation applicable to both cotton and woollen fabrics and capable of large-scale adaptation. In this method the fabric is first immersed in a solution of a soluble disinfectant—such as phenyl mercuric acetate—and this is followed by treatment with a solution capable of precipitating the disinfectant within the textile fibres in a relatively insoluble form: in the example quoted, sodium bromide would precipitate phenyl mercuric bromide.

A disinfectant suitable for this purpose would have to possess a very high phenol coefficient, as relatively little would diffuse out, and it would also require to be non-toxic. Preliminary tests with phenyl mercuric bromide have shown that a practical disinfecting action can be obtained on cotton handkerchiefs, but further investigation is necessary to exclude the possibility of toxic or irritant effects of this substance.

Although this method is still in the experimental stage, we thought its inherent possibilities and its potential importance in public health of sufficient interest to bring to your notice.

Tuberculosis in Lancashire

IN 1946 only 3·7% of all deaths in Lancashire were due to tuberculosis. Notifications of new pulmonary cases, which apart from a check in 1945 have risen steadily since 1939, reached 1663, the highest figure since 1927; men between 20 and 34 were chiefly affected, and Dr. F. S. Bradbury,[1] the central consultant tuberculosis officer, mentions the probable influence of war service in some of these cases. Deaths from pulmonary tuberculosis, though more numerous than in 1945, were lower than in the previous year. The chief rise in both sexes was in the age-group 35–44, whose responsibilities are most likely to interfere with treatment. In the age-group 15–24 there was a 13% reduction in pulmonary deaths: and this is attributed to earlier discovery of cases, in which mass radiography is held to have played a leading part. Notifications of non-pulmonary cases were only 104, the lowest figure on record, and 16% less than in 1945. Deaths from non-pulmonary tuberculosis also reached a new low record.

Sanatoriums were hampered by lack of staff, but have somehow managed to keep their beds full and their waiting-lists fairly short. In September, 1947, the completed and that the histological studies were being continued.

[1] Report of the Tuberculosis Services of the Lancashire County Council. 1946. Preston: T. Snape. 1947. Pp. 42.

Such then was the declared stage when my letter appeared (*Lancet*, 1946, ii, 436) in which, following argument and examples, anatomical, physiological, and pathological, and finally mathematical, I stated :

> "... from a consideration of the hæmodynamics of the renal circulation in the rabbit, it is possible to suggest that the degree and character of the altered renal circulation, as outlined by Dr. Trueta and his colleagues, and the 'redistribution of blood-flow within the kidney' discussed by Professor Maegraith (p. 213), could be maintained by a circulation via the deep (subcortical or juxtamedullary) glomeruli only, the cortex being relatively avascular, by vasoconstriction of the peripheral arterial vessels in response to afferent (sciatic or other) stimuli."

My experimental work was first reported to, and demonstrated at, a meeting of the Pathological Society of Great Britain and Ireland held in July, 1941. This was the year in which I described the *juxtamedullary glomeruli*, as I mentioned at the recent meeting of the Royal Society of Medicine.

SPIRILLUM MINUS TREATMENT OF G.P.I.

SIR,—The records of the experiment in therapy described here were lost during the Malayan campaign. Dr. W. R. Logan, who investigated the cases clinically and made elaborate records of the progress of the patients, lost his life at the Alexandra Hospital when it was stormed by Japanese troops a few days before the surrender of Singapore. His death was a serious loss to psychiatry in the Far East and to many friends who appreciated his ability and personal charm.

General paralysis of the insane (G.P.I.) is by no means rare in the Federated Malay States. In 1940–41, when this investigation was carried out, we identified more than 100 cases by clinical and serological criteria in a population of rather more than 3000 patients at the Central Mental Hospital. The patients included Chinese, Malays, and Indians, the first-named predominating. Syphilis is prevalent among the Chinese and Indians in the cities and towns, but relatively uncommon among the riverine Malays, who are however subject to yaws.

The treatment of G.P.I. in Malaya presented two special difficulties. First, patients seldom reached the Central Mental Hospital until they were in an advanced state of physical and mental deterioration. Most of them had received no antisyphilitic therapy since they were first infected. About half the cases in this experiment were beyond treatment and could only be regarded as forlorn hopes. Only a few patients, who had held clerical appointments in the government service or had been in some other position that brought them to hospital relatively early in the course of their complaint, could be considered in any way promising material. The second difficulty was that most of the patients had had malaria, wherefore the possibility of successful malaria therapy was remote. Further, in the presence of anopheline mosquitoes capable of transmitting malaria there was the risk that other patients might be accidentally infected. Since we had no apparatus for inducing hyperpyrexia, we had to try some other method.

Sporadic cases of rat-bite fever (sodoku) are not uncommon in Malaya. During the latter part of 1940 one of us (J. O. P.) saw 2 cases. In the first case, though cultural methods failed, the infection was easily established in guineapigs. Two experimental infections made with guineapig blood did not give rise to an adequate fever, and this strain, though maintained for a while, was not used again. In the second case the infection was again established in guineapigs. Since this strain appeared to be more virulent it was used for the remainder of the experimental infections of cases of G.P.I.

No difficulty was encountered in maintaining the strains by passage in guineapigs. The animals were inoculated by the intraperitoneal route and about a week later became feverish, their eyes bloodshot, and their appetites poor. For one or two months their condition would slowly deteriorate, with loss of weight and an increasingly mangy appearance. They were then killed, and blood or liver emulsion from them was introduced into other animals. In this way an ample supply of blood for the inoculation of patients was always available.

Spirillum minus was repeatedly identified in the blood and livers of the guineapigs, both in wet and in stained preparations. The morphology of the two strains appeared t be identical, the spirilla varying greatly in length, number o spirals, and number of flagella.

Forty experimental human infections had been completed when war ended the investigation. In the firs 6 cases guineapig blood was introduced into the skin o the arm. In 2 of these cases the development of feve was accompanied by serious ulceration spreading from the point of inoculation. In one case the ulcer sprea until its diameter was about 6 in. and it had involve the underlying muscle to such a degree that the humeru was almost exposed. The healing that followed treatment with neoarsphenamine was remarkable, the scarrin being far less than one could have believed possible This method of introducing the infection was abandoned and in the remaining cases a few drops of guineapi blood or liver emulsion diluted ten times with salin were injected into the antecubital vein with a fin needle, every effort being made not to allow any of th infected fluid to contaminate the skin or subcutaneou tissue. In a few cases a small ulcer developed at th site of inoculation, but in the remainder there was littl or no local reaction.

The incubation period was seven or eight days in nearly a cases. A few patients had premonitory symptoms on th fifth or sixth day, and in a few others the onset of symptom was delayed by a few days. Only in two or three cases wa there a failure to infect at the first attempt, and in non of these was a second inoculation unsuccessful. The feve produced was satisfactory in a high proportion of case reaching a peak of 104°F, usually on the third evening afte the onset of symptoms. In 2 cases a maximal temperatur of 106°F was achieved. The fever was accompanied b considerable prostration, and the condition of some of th patients at this time was rather alarming because of thei collapsed state and rapid and almost imperceptible pulse yet no patient died during the febrile phase, and the recover in their condition as the fever passed was remarkable. Th temperature never remained high for more than 72 hours.

Most of the patients showed the typical dusky macul papular rash during the fever, and in a few instances a h bath revived the rash a day or two after it had apparentl cleared. In those cases in which a leucocyte-count was mad during fever there was a well-marked neutrophil leucocytos and often an increased proportion of eosinophils. The secon bout of fever usually occurred about the sixth day after th first and was usually as severe as the first and in a few instance more severe. In most cases the third cycle showed a fallin off, and it was our usual practice to terminate the infectio the day before the fourth or fifth rise of temperature wa expected. In some cases one injection of neoarsphenamin 0·5 g. was insufficient, and in a week or so the temperatur rose again. Three injections of 0·5 g. at intervals of five day never failed to terminate the infection.

Albuminuria was usually present during the pyrexi period, often with casts, and it tended to persist, thoug diminishing, even after the fever had been terminated. Fou patients died in uræmia, and the tendency to a progressiv nephritis was a serious drawback to this method of feve therapy. In view of the fact that *Treponema pallidum* *Sp. minus*, and arsenic all have a predilection for inflictin renal damage it is perhaps surprising that there were not mor deaths from uræmia. It is most unfortunate that the organ removed post mortem from these cases and preserved wer never studied.

In about 6 cases spectacular improvement in the ment condition was judged by Dr. Logan to have taken plac One previously intelligent Malay, who had held a positio of some responsibility in the government service and though in an early stage of dementia at the time o treatment, was in good physical condition, apparentl recovered completely ; but his subsequent history i unknown. Some other patients also showed evidenc of improvement. For about half the patients, many to advanced to be a fair test of the treatment, the onl result was a further decline in their physical condition

J. ORDE POYNTON.

Adelaide.

aggravated the condition and therefore the claim failed. There was a similar result in the case of X.Y. v. Minister of Pensions last December. A soldier on embarkation leave had refused his fiancée's request that he should marry her before he went overseas. On return to his unit he received a letter from her in which she broke off the engagement. Four days later he shot himself in a military camp with a Service revolver. The pensions appeal tribunal held his death not to be attributable to war service. A military court of inquiry found that he met his death by his own hand while the balance of his mind was disturbed. The Ministry contended that the issue to him of a revolver and ammunition was an occasion for him to turn them against himself but not the cause of his so doing. The judge ruled that the cause was his trouble with his fiancée, a factor entirely extrinsic and unrelated to his Service life. These two cases perhaps were easier to decide, but even here the popular verdict might have gone the other way.

Parliament

FROM THE PRESS GALLERY

More about Our Calories

In the House of Commons on Nov. 17, on the motion for the adjournment, Mr. E. P. SMITH pointed out that the British Medical Association's report on nutrition in 1933 demanded 3400 calories as the minimum daily diet to maintain working efficiency, and for people doing heavy work 3500–4000 calories were thought desirable. In his brave but dispiriting speech on the Address, Sir Stafford Cripps had assessed our average daily intake of calories at 2870 which he admitted would have to be reduced. Mr. Smith thought that that reduction had probably taken place since the introduction of potato rationing. The Ministry of Food had stated that from rationed and pointed foodstuffs our daily average intake was 1530 calories, but very few of us, Mr. Smith believed, could in fact obtain the other 1340 calories from unrationed foodstuffs. The system of calculation used by the Ministry of Food had the essential demerit of over-simplicity. It consisted in dividing the amount of unrationed food consumed in the country—itself a notional figure—by the number of the population: and it included all meals consumed in restaurants and canteens, so that a poor old couple in a country village, who had no access to restaurants or canteens, were estimated to be receiving 2870 calories daily when, in fact, their intake was probably less than 2000 calories. A man in gaol, Mr. Smith concluded, received 2923–2955 calories daily, and a woman 2541–2605 calories: a boy in a borstal institution 2987–3051, and a girl 2521–2585 calories daily. In a dietetic sense, therefore, it paid nowadays to be an inhabitant of a gaol.

Dr. EDITH SUMMERSKILL, parliamentary secretary to the Ministry of Food, reminded Mr. Smith that the method of taking the amount of food consumed and dividing it by the population was devised not by her department but by the Scientific Committee set up during the Coalition Government by the Combined Food Board. Whatever its shortcomings it was a valuable means of comparing one period with another and the conditions prevailing in one period with those prevailing in another.

She also thought that Mr. Smith did not appreciate that the consumption levels quoted by her department were generally the average because they were asked for the average. There were of course wide variations in individual intake; when it was suggested the average calorie intake of the whole population was 2800, that included the intake of 900 calories by an infant and 4500 by a heavy worker. In quoting the number of calories consumed by a prisoner Mr. Smith was taking a specific number of calories consumed by one man doing a particular job. That could not be justly compared with an average for the whole country. Again, the average intake of an adult man might vary from 2500 calories to 4700 calories daily, and of an adult woman from 2000 to 3000 calories. The nursing mother, for instance, got 3000 calories a day. One hot meal a day, Dr. Summerskill added, equalled 900 calories, and one snack 500 calories, and when the average of a family was taken, it must be remembered that where the wage-earner was feeding outside the food he would otherwise consume was consumed by the family.

QUESTION TIME

Source of Our Calories

Mr. G. R. CHETWYND asked the Minister of Food whether he would give the calorie content of the no. 2 diet suggested for an adult man by the British Medical Association in 1933: and of the present average diet in the following proportions: proteins, fats, and carbohydrates.—Dr. E. SUMMERSKILL replied: Of the 3386 calories in the B.M.A. diet no. 2, 12% were derived from protein, 28% from fat, and 60% from carbohydrate. The corresponding proportions in the present-day average diet are 12%, 33%, and 55% respectively.

Rehabilitation Centres in Scotland

Mr. E. G. WILLIS asked the Minister of Labour if he would consider the establishment of an Industrial Rehabilitation Centre in Scotland.—Mr. NESS EDWARDS replied: It is hoped to open early in 1948 two industrial rehabilitation units attached to Government training centres in Scotland: one at Hillington, Glasgow, and one at Granton, Edinburgh. Each unit will have accommodation on a non-residential basis for 100 persons.

Government Grants for Cancer Research

Mr. P. FREEMAN asked the Lord President of the Council what was the total grant made from Government funds for the purpose of cancer research in each of the last 20 years; and in what form it was proposed to continue these grants after the Public Health Act, 1947, came into operation.—Mr. H. MORRISON replied: Expenditure on cancer research from the parliamentary grant-in-aid for the work of the Medical Research Council has been at the rate of approximately £6000 per annum during the greater part of the period mentioned, this provision being of course supplementary to the much larger expenditure from the endowments and other resources of unofficial organisations concerned with this particular field. Expenditure from the same source in the financial year 1946–47 was about £12,000, and expenditure in the present financial year is estimated at £31,000 (including £14,000 of a non-recurrent nature). Substantial additional expenditure in the future has been approved for research on applications of atomic physics to the treatment of cancer. These activities are not affected by the National Health Service Act, 1946.

Mr. SOMERVILLE HASTINGS: Is the sum mentioned sufficient for the legitimate demands of those who are engaged in this research?—Mr. MORRISON: I think so, in the light of the useful activities which can be conducted. Considerable sums are being spent elsewhere in the field of research under the auspices of the Ministry of Health, hospitals, and what not. I do not think there is any difficulty about money, but I would be prepared to consider further developments if useful avenues of research were available to us.

Future of Private Homes

Mr. H. CHANNON asked the Minister of Health whether, in drawing up detailed plans for the National Health Service, he could give an assurance that everything would be done to assist and encourage the provision of private registered nursing and maternity homes to supplement the main hospital scheme.—Mr. A. BEVAN replied: Private homes are outside the scope of the National Health Service Act, and their future must therefore depend on the demand for private treatment outside the service.

Accommodation for Mental Defectives

Mr. W. R. SORENSEN asked the Minister what progress had been made during the past twelve months in providing accommodation for mental deficients; and approximately how many mental deficients were now awaiting suitable institutional accommodation.—Mr. BEVAN replied: Premises acquired by local authorities will provide 160 beds in the immediate future. Further accommodation will be available in the new year in three mental deficiency colonies released by Service departments. Mental defectives awaiting institutional accommodation were 3890 on Jan. 1 last.

waiting-list was 138 for the county, representing 10% of the number of beds occupied; and this percentage is much lower than the figure for England and Wales as a whole.

Poliomyelitis and Polioencephalitis

During the week ended Nov. 15 the fall in notifications of poliomyelitis, 186 (198), was again small, and there was a slight rise in those of polioencephalitis, 15 (12). Figures for the previous week are shown in parentheses. Notifications of poliomyelitis in London were 12 (16); and there was a small reduction in most of the southern counties except Kent 15 (4) and East Sussex 9 (3). The northern counties also showed reductions for the most part, but there was a slight upward trend in East Anglia and the west.

Infectious Disease in England and Wales

WEEK ENDED NOV. 15

Notifications.—Smallpox, 0; scarlet fever, 1947; whooping-cough, 1217; diphtheria, 195; paratyphoid, 8; typhoid, 11; measles (excluding rubella), 2355; pneumonia (primary or influenzal), 582; cerebrospinal fever, 40; poliomyelitis, 186; polioencephalitis, 15; encephalitis lethargica, 2; dysentery, 95; puerperal pyrexia, 117; ophthalmia neonatorum, 58. No case of cholera, plague, or typhus was notified during the week

Deaths.—In 126 great towns there were no deaths from enteric fever, 2 (0) from measles, 3 (1) from scarlet fever, 3 (0) from whooping-cough, 2 (1) from diphtheria, 61 (4) from diarrhœa and enteritis under two years, and 13 (2) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 196 (corresponding to a rate of 25 per thousand total births), including 28 in London.

Medicine and the Law

Death or Injury "attributable to war service"

IN a lengthening series of appeals under the Pensions Appeal Tribunals Act of 1943 Mr. Justice Denning has had to decide whether a death or injury was "attributable to war service." This is not exclusively a medical question; the element of causation introduces arguments on which an appeal tribunal may misdirect itself. Two recent cases, decided in the present month, illustrate the difficulty. In one a man who had served in a balloon crew claimed that his hernia was a war injury. The conditions of his duty exposed him to the catching of a cold; he developed a cough, and a fit of coughing produced the rupture. One cause, perhaps a predominant cause, was the weakness of the abdominal wall: but one of the operative causes was his war service, and he was allowed a pension. In the other recent case, Monaghan *v.* Minister of Pensions, a man, 42 years of age, was working in Holland in the Pioneer Corps on the erection of a Bailey bridge. Some Canadians, it was alleged, gave the pioneers some gin, saying that it came from an abandoned Red Cross barge; the man drank and died two days later in hospital, having been admitted suffering from gin poisoning. The judge held that the cause of death was the drinking of raw spirit, an act entirely within his own personal sphere; the war service was only part of the surrounding circumstances. The pensions appeal tribunal rejected the widow's claim, and the judge refused to interfere.

Monaghan's case indeed was not unlike the Wedderspoon case, decided some months earlier, where a surgeon lieutenant on board his ship took a dose of chloral hydrate because he suffered from insomnia. He died in his sleep; post-mortem examination showed that he suffered from a weak heart. Mr. Justice Denning held death not to be attributable to war service. If the doctor had carelessly given an overdose to a member of the ship's company, the man's death would have been attributable to war service. But this dose was taken by the deceased in prescribing for himself. It was "the case of a man, who happened to be a doctor, taking too large a sleeping draught in his personal capacity . . . no more attributable to war service than the consequences of drinking too much or playing a game of squash."

The element of casuistry is intriguing. The leading decision of the judge is the Chennell case of last year. A boy found an incendiary bomb, took it into a Chertsey street, and played with it. There was an explosion whic injured a girl who was passing by. The Ministry rejecte her claim that it was a war injury entitling her to com pensation. The pensions appeal tribunal allowed th claim and the judge approved. The dropping of th bomb by the enemy was a cause; the boy's inter ference was not so powerful an intervening cause as t supersede it.

The problems of causation are probably hardest whe the ætiology of a disease is uncertain. A year ago, i the Donovan case, the judge found himself able to allo the widow's claim where her husband had died fr Hodgkin's disease. Recently, in James *v.* Minister Pensions, there was evidence that the claimant had swelling on the right side of his neck which graduall spread. He was sent to hospital, where Hodgkin disease was diagnosed; he was then discharged from th Army on this account. He claimed a war pensio having apparently heard of the Donovan decision. H case, said the judge, was shortly and simply this: " I have never known any illness prior to entering th Forces, and as medical science has not been able to fin out how Hodgkin's disease is contracted, I think I hav more right to say that it is due to war service than yo have in saying it is not!" His claim was rejected by th Ministry; he died, and his widow claimed again in vai The claim was out of time and the right to a rehearin required decision, so that the final result is still awaite In giving leave to appeal, the judge observed that would be hard if Donovan's claim succeeded and that James was rejected.

Can medical science establish that cancer is a disea attributable to war service? In Miller *v.* Minister Pensions, decided last July, the illness of an Arm officer serving in the Middle East had been diagnosed carcinoma of the œsophagus. He was flown back England and died soon after his arrival. The clai was regarded as a test case and was referred to S Ernest Rock Carling as an independent medical expe The pensions appeal tribunal concluded that the prob bilities as a whole were that war service played no pa in the disease, though it was recognised that there was possibility the other way. The judge, reviewing th evidence and some previous decisions, observed that th ætiology of disseminated sclerosis was unknown, b experience indicated that external factors could influen its onset and development; claims in respect of th disease had therefore been allowed. On the other ha schizophrenia seemed likely to be, in the great majori of cases, essentially independent of external cause claims in respect of schizophrenia had therefore be rejected. "If nothing else appears except that t cause [of death or injury] is unknown, then the on proper conclusion is that the Minister cannot dischar the burden of proof, because the unknown cause may a cause incidental to war service."

Finally two neurosis cases may be mentioned. T facts in W. *v.* Minister of Pensions (1946) were that man was discharged from the Army as permanent unfit by reason of severe and chronic anxiety due to h domestic marital affairs. Here the judge held that t war service played no active part; the neurosis w caused by the wife's conduct: his war service had n aggravated the condition and therefore the claim failed. There was a similar result in the case of X.Y. *v.* Minister Pensions last December. A soldier on embarkation ave had refused his fiancée's request that he should arry her before he went oversea. On return to his nit he received a letter from her in which she broke off e engagement. Four days later he shot himself in a ilitary camp with a Service revolver. The pensions peal tribunal held his death not to be attributable to r service. A military court of inquiry found that he et his death by his own hand while the balance of his ind was disturbed. The Ministry contended that the ue to him of a revolver and ammunition was an casion for him to turn them against himself but not e cause of his so doing. The judge ruled that the use was his trouble with his fiancée, a factor entirely trinsic and unrelated to his Service life. These two es perhaps were easier to decide, but even here the pular verdict might have gone the other way.

More about Our Calories

In the House of Commons on Nov. 17, on the motion f the adjournment, Mr. E. P. Smith pointed out that e British Medical Association's report on nutrition 1933 demanded 3400 calories as the minimum daily et to maintain working efficiency, and for people doing avy work 3500–4000 calories were thought desirable. In his brave but dispiriting speech on the Address, r Stafford Cripps had assessed our average daily intake calories at 2870 which he admitted would have to be duced. Mr. Smith thought that that reduction had obably taken place since the introduction of potato tioning. The Ministry of Food had stated that from tioned and pointed foodstuffs our daily average take was 1530 calories, but very few of us, Mr. Smith lieved, could in fact obtain the other 1340 calories om unrationed foodstuffs. The system of calculation ed by the Ministry of Food had the essential demerit f over-simplicity. It consisted in dividing the amount f unrationed food consumed in the country—itself a otional figure—by the number of the population; d it included all meals consumed in restaurants and nteens, so that a poor old couple in a country village, ho had no access to restaurants or canteens, were timated to be receiving 2870 calories daily when, in ct, their intake was probably less than 2000 calories. man in gaol, Mr. Smith concluded, received 2923–2955 lories daily, and a woman 2541–2605 calories; a boy a borstal institution 2987–3051, and a girl 2521–2585 lories daily. In a dietetic sense, therefore, it paid owadays to be an inhabitant of a gaol.

Dr. Edith Summerskill, parliamentary secretary o the Ministry of Food, reminded Mr. Smith that the ethod of taking the amount of food consumed and ividing it by the population was devised not by her partment but by the Scientific Committee set up during he Coalition Government by the Combined Food Board. hatever its shortcomings it was a valuable means of omparing one period with another and the conditions revailing in one period with those prevailing in nother.

She also thought that Mr. Smith did not appreciate hat the consumption levels quoted by her department ere generally the average because they were asked or the average. There were of course wide variations n individual intake; when it was suggested the average alorie intake of the whole population was 2800, that ncluded the intake of 900 calories by an infant and 4500 y a heavy worker. In quoting the number of calories onsumed by a prisoner Mr. Smith was taking a specific umber of calories consumed by one man doing a articular job. That could not be justly compared with n average for the whole country. Again, the average ntake of an adult man might vary from 2500 calories to 00 calories daily, and of an adult woman from 2000 to 3000 calories. The nursing mother, for instance, got 3000 calories a day. One hot meal a day, Dr. Summerskill added, equalled 900 calories, and one snack 500 calories. and when the average of a family was taken, it must be remembered that where the wage-earner was feeding outside the food he would otherwise consume was consumed by the family.

QUESTION TIME

Source of Our Calories

Mr. G. R. Chetwynd asked the Minister of Food whether he would give the calorie content of the no. 2 diet suggested for an adult man by the British Medical Association in 1933; and of the present average diet in the following proportions: proteins, fats, and carbohydrates.—Dr. E. Summerskill replied: Of the 3386 calories in the B.M.A. diet no. 2,12% were derived from protein, 28% from fat, and 60% from carbohydrate. The corresponding proportions in the present-day average diet are 12%, 33%, and 55% respectively.

Rehabilitation Centres in Scotland

Mr. E. G. Willis asked the Minister of Labour if he would consider the establishment of an Industrial Rehabilitation Centre in Scotland.—Mr. Ness Edwards replied: It is hoped to open early in 1948 two industrial rehabilitation units attached to Government training centres in Scotland; one at Hillington, Glasgow, and one at Granton, Edinburgh. Each unit will have accommodation on a non-residential basis for 100 persons.

Government Grants for Cancer Research

Mr. P. Freeman asked the Lord President of the Council what was the total grant made from Government funds for the purpose of cancer research in each of the last 20 years; and in what form it was proposed to continue these grants after the Public Health Act, 1947, came into operation.—Mr. H. Morrison replied: Expenditure on cancer research from the parliamentary grant-in-aid for the work of the Medical Research Council has been at the rate of approximately £6000 per annum during the greater part of the period mentioned, this provision being of course supplementary to the much larger expenditure from the endowments and other resources of unofficial organisations concerned with this particular field. Expenditure from the same source in the financial year 1946–47 was about £12,000, and expenditure in the present financial year is estimated at £31,000 (including £14,000 of a non-recurrent nature). Substantial additional expenditure in the future has been approved for research on applications of atomic physics to the treatment of cancer. These activities are not affected by the National Health Service Act, 1946.

Mr. Somerville Hastings: Is the sum mentioned sufficient for the legitimate demands of those who are engaged in this research?—Mr. Morrison: I think so, in the light of the useful activities which can be conducted. Considerable sums are being spent elsewhere in the field of research under the auspices of the Ministry of Health, hospitals, and what not. I do not think there is any difficulty about money, but I would be prepared to consider further developments if useful avenues of research were available to us.

Future of Private Homes

Mr. H. Channon asked the Minister of Health whether, in drawing up detailed plans for the National Health Service, he could give an assurance that everything would be done to assist and encourage the provision of private registered nursing and maternity homes to supplement the main hospital scheme.—Mr. A. Bevan replied: Private homes are outside the scope of the National Health Service Act, and their future must therefore depend on the demand for private treatment outside the service.

Accommodation for Mental Defectives

Mr. W. R. Sorensen asked the Minister what progress had been made during the past twelve months in providing accommodation for mental deficients; and approximately how many mental deficients were now awaiting suitable institutional accommodation.—Mr. Bevan replied: Premises acquired by local authorities will provide 160 beds in the immediate future. Further accommodation will be available in the new year in three mental deficiency colonies released by Service departments. Mental defectives awaiting institutional accommodation were 3890 on Jan. 1 last.

Obituary

WILLIAM SEAMAN BAINBRIDGE

M.D., SC.D.

WE have received from Mr. Sampson Handley the following tribute to Dr. W. S. Bainbridge of New York, who died on Sept. 22. "In the years before the first world war," Mr. Handley writes, "Bainbridge was a frequent visitor to Europe, and wherever he went his kindly personality, his abounding energy, his open-mindedness, and his genius for friendship made him the welcome ambassador of American to European surgery. Dr. Bainbridge's book, *The Cancer Problem*, gave a catholic account of its subject, with full and fair recognition of English workers, such as Bashford, Murray, and Lazarus-Barlow, and of the clinical work of British and Continental surgeons and of its author. It was translated into French, Italian, Spanish, Polish, and Arabic. In both world wars he served in the American Navy, and as medical inspector and commander Reserve Force had much to do with the training of young American naval surgeons. His many honours, governmental and academic, included decorations from 18 nations. Bainbridge lived a full life, and his work survives him to mould the future."

ROBERT CARMICHAEL WOOD

M.B. EDIN., M.R.C.P.E.

Dr. R. C. Wood, who died on Nov. 23, graduated at the University of Edinburgh in 1932 and took his M.R.C.P.E. four years later. After qualifying he held resident appointments in Edinburgh at the Royal Maternity Hospital, the Hospital for Sick Children, and the Royal Infirmary. During the late war he served in the R.A.M.C., with the rank of major, as a medical specialist at a general hospital in the Middle East, and in 1945 (with K. C. Dixon) he published a paper on tick-borne relapsing fever in Cyprus.

G. A. G. P. and R. W. D. T. write: "Many war-time friends will regret the early death of Bertie Wood, in addition to the wide circle in Edinburgh and, of course, his patients. He had more than his share of service overseas and none longed more deeply to be home again. In those trying days he was a great colleague; not only a good physician, hard working, reliable, and loyal, but one of those whose companionship made all the difference to his friends. We shall miss him sadly down the years."

Births, Marriages, and Deaths

BIRTHS

COX.—On Nov. 14, the wife of Dr. P. J. N. Cox—a daughter.

EVANS.—On Nov. 11, at Worcester Park, the wife of Dr. E. A. Evans—a son.

GARROD.—On Nov. 19, in London, the wife of Dr. Oliver Garrod—a son.

KING.—On Nov. 19, at Wellington, New Zealand, the wife of Dr. A. S. King—a son.

LISTER.—On Nov. 17, the wife of Mr. Arthur Lister, F.R.C.S.—a son.

PALEY.—On Nov. 16, the wife of Dr. R. G. Paley—a daughter.

TODD.—On Nov. 14, at Bath, the wife of Dr. W. A. Todd—a daughter.

MARRIAGES

BROADBENT—LLOYD.—On Nov. 15, John Dennis Broadbent, M.R.C.S., to Judith Lloyd.

BUSH—FARNSWORTH.—On Nov. 1, at West Norwood, John Peter Bush, M.R.C.S., to Edith Mary Farnsworth.

NICHOLSON—MARSHALL.—On Nov. 15, David Percy Nicholson, M.B., to Mary Marshall.

WHOWELL—MURRAY.—On Nov. 15, in London, William Brian Whowell, M.B., to Joy Murray.

DEATHS

ATKINSON-FLEMING.—On Nov. 14, in London, Frederick Charles Atkinson-Fleming, M.C., B.A., M.B. Dubl., major, R.A.M.C. retd.

BENTALL.—On Nov. 16, William Charles Bentall, O.B.E., F.R.C.S.E., aged 72.

COSGROVE.—On Nov. 17, at Sydney, Australia, Charles Cosgrove, M.C., L.R.C.P.E.

EAVES.—On Nov. 21, Elizabeth Cowper Eaves, M.D. Lond., D.P.M.

FARQUHARSON.—On Nov. 16, in London, George Sinclair Farquharson, M.B. Lond., aged 84.

KNIGHT.—On Nov. 18, at Painswick, Charles Voughton Knight, M.D. Lond., aged 75.

MOFFAT.—Robert Unwin Moffat, C.M.G., M.D. Edin.

MONTGOMERY.—On Nov. 19, at Wolstanton, Staffs, Anna Pauline Montgomery, M.D. Lond.

Notes and News

COMMITTEE ON CERTIFICATES ISSUED BY PRACTITIONERS

A COMMITTEE has been appointed jointly by the Ministe of Health and the Secretary of State for Scotland to investigat "how far it would be practicable to reduce the number o certificates to be signed by medical practitioners." Th committee comprises: Mr. Archibald Safford, recorder o Faversham (chairman); Dr. J. C. Arthur, Gateshead; Mi Florence Hancock, chairman of the general council of th Trades Union Congress; Dr. Walter Jope, Glasgow; Mr. A. W Neville, former principal assistant secretary in the Ministr of Health; and Mr. R. L. Briggs, Ministry of Healt (secretary). The medical members were nominated by th British Medical Association.

FOOD AND HEALTH

IN the latest edition of his textbook[1] Prof. Henry C Sherman, of New York, makes some points that are especiall germane to the present situation. Having spent a life-tim thinking and writing on his subject, he looks at the wood a well as the trees, and the landscape as well as the woo He is attracted to Smuts's "holism," pointing out that evolu tion has proceeded among organisms availing themselv of the whole of other living organisms, and suggests th we are flying in the face of nature if we make use of highl refined commercial food products. Instead of asking for, an providing, more protein, calories, vitamins, and miner elements, we should demand more milk, eggs, fish, fruit, an green vegetables—whole foods rather than their chemic constituents.

What is the advantage of adopting sound nutrition Professor Sherman gives many answers, one of them quantit tive. At Harvard, he says, King found that the chance an infant being essentially a perfect specimen and showin robust health was four times greater when the mother's di had been superior (graded "good" or "excellent"); an that the risk that the infant would have a low health ratin was twenty times greater when the mother's diet had bee inferior (graded "poor" or "very poor"). If these Harva findings applied throughout the country, better nutrition American homes would mean that well over a million babi each year would start their lives at a higher health level.

To those pessimists who fear the tendency among civilis peoples towards communities with an excess of middle-ag and elderly people, he points out that individuals most oft attain their opportunities for highest service at about 45- years of age—i.e., when there remains but a third of t traditional span. The shortness of individual lives sets limit to the actual use by man of the knowledge he h accumulated and the institutions he has built and develope Sound life-long nutrition adds to the period of the flowerin and fruiting of human intelligence, and therefore to t permanent well-being of the human race—a stimulati thought for those "past meridian."

HOMES OF ST. GILES

THE dread of the leper is largely misplaced. As we ha lately noted,[2] only a small proportion of lepers are ev potentially infective, and of the two or three hundred in th country the few who are infective can be taught to mana their disease so that it is not dangerous to others. For tho who are unable to live at home one small colony exists—t Homes of St. Giles. This little-known charity was found in 1914, and in an account of it[3] Dr. J. M. H. MacLeo the chairman, tells how it was first housed in tempora buildings on a small farm in Essex. Now the tempora buildings have given place to comfortable brick bungalow each with its own bed-sitting-room, kitchenette, and bathroo A larger communal bungalow houses dining-room and kitche and a medical bungalow is equipped with an operating-roo The recreation hall is furnished with a billiards-table and stage, and the patients have wireless sets in their bungalow Occasionally the wives of non-infective patients are able come to live with their husbands in the bungalows, a share in the nursing and domestic work of the colony. The also a guest-house, and a chapel has been made in the farmstead barn.

[3] The Homes of St. Giles for British Lepers. 1947. Obtainal from the secretary, 170, Bishopsgate, London, E.C.2.

The medical work is done by two visiting medical officers who live near by, advised by consultants from London. The nursing, originally undertaken by an Anglican sisterhood, is now the charge of sisters from the community of the Sacred Passion who have the care of lepers in East Africa. At present the homes take 10 men and 3 women, and also has a few non-infective cases as outpatients, and nearly [illegible] patients have been treated since the homes opened.

The homes are a limited-liability company trading without profit, and are managed by an executive committee appointed by a council. Unaided by any Government grant, they depend for support on subscriptions and donations. Hard times are affecting the means, though probably not the will, of givers, and new subscribers are urgently needed. Those who wish to help should send their contributions to Mr. [illegible] Stanley, the secretary, at 170, Bishopsgate, London, E.C.2.

KEEPING THE ENGINE WARM

A MECHANICALLY minded peripatetic correspondent, writing in 1942,[1] urged some enterprising manufacturer of electrical equipment to produce a gadget for starting a car off the mains—via a 12-volt transformer—and at the same time keeping the engine really hot when not in use by means of immersion heaters in the radiator. His hopes have partly been fulfilled, for immersion heaters for the radiator are now on the market. A simple form is that made by Messrs. [illegible] Electrical Products, of Manchester, in which the heater screws into the hole for the drain tap at the bottom of the radiator. When the car is in the garage the heater is connected to the mains, via a 12-volt transformer which also keeps the battery charged. If the car is left standing in a car-park or elsewhere the heater can be worked by the battery. The current consumption is 100 watts from the mains and 300 watts from the battery. Apart from ensuring easy starting such an immersion heater should save the petrol used in warming up the engine.

Two simpler types of heater are worth considering, though they will not charge the battery. One—"Peter the Heater"—hangs inside the bonnet like a Davy lamp. Made by L. G. [illegible], of Drury Lane, it consists of an element enclosed in a perforated cage, and runs from a light plug. The other is the Belling Air-warmer, a non-luminous type of heater made in cast-iron, which can be fixed horizontally to the garage wall. A number of projecting fins provide a large heating surface, and this device is both compact and safe. To the doctor who has often to start his car in the middle of the night even in winter, a heater is a valuable ally.

University of Cambridge

On Nov. 15 the degree of M.D. was conferred on E. B. [illegible] and N. D. Compston.

University of Sheffield

Prof. H. N. Green, who occupies the chair of pathology, has been granted the additional title of director of cancer research.

Having retired from the position of medical officer of health for Sheffield, Dr. John Rennie has resigned from the university chair of public health.

Royal College of Surgeons of England

A course of 72 lectures on anatomy, applied physiology, and pathology will be given at the college from April 5 to May 25 daily at 3.45 and 5 P.M. Practical demonstrations in these subjects will also be held daily from March 22 to June 11 from 10 A.M. to 1 P.M., and from 2 to 3.30 P.M. The demonstrations will only be open to those attending the lectures and will be limited to 40 students: preference will be given to those unable to obtain practical instruction elsewhere, and to ex-Servicemen. Applications should be sent to the secretary of the postgraduate education committee of the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, before Feb. 2 for the demonstrations, and before April 3 for the lectures.

Owing to the rise in costs, from Jan. 1 the charge for the monthly college dinners will be increased from £1 1s. to £1 5s.

Royal Institute of Philosophy

The King has accorded the title of Royal to the British Institute of Philosophy.

British Association of Allergists

At a meeting held at Oxford on Nov. 15, it was decided to form this association, and the first general meeting will take place at St. Mary's Hospital, London, on Jan. 24. The speakers will include Dr. John Freeman and Mr. Frank Coke. Dr. A. W. Frankland, Wright-Fleming Institute of Microbiology, St. Mary's Hospital, Paddington, W.2, is the secretary of the new association.

Production of Penicillin

The penicillin factory at Speke which has been operated by the Distillers Company, as agents for the Minister of Supply, since December, 1945, will become a commercial undertaking on Dec. 1. A new company, the Distillers Company (Biochemicals) Ltd., has been formed especially for the purpose, and arrangements have been made for the entire output of penicillin (sodium and calcium salts), to be distributed by the following pharmaceutical houses: Allen & Hanburys, Boots Pure Drug Co., The British Drug Houses, Burroughs Wellcome & Co., Evans Medical Supplies, Imperial Chemical (Pharmaceuticals), Pharmaceutical Specialities (May & Baker).

Specialist Appointments in the L.C.C. Service

The London County Council last week approved a scheme for the enlargement of specialist staffs in the council's hospitals. In general, one position of medical superintendent, deputy medical superintendent, or senior resident medical officer has been abolished for each new specialist position. The following promotions have been made:

Senior physicians (superintendents), on a salary scale of £1500–£100–£1800 and house valued at £150 or allowance in lieu:

J. C. Evans, M.R.C.P., W. Feldman, M.R.C.P., W. G. Sears, M.R.C.P., B. A. Young, M.R.C.P. (all commencing at £1800).

Senior physicians (deputies to superintendents), on a salary scale of £1500–£100–£1800 with no emoluments and £50 a year as deputy:

Major H. C. Aston, M.R.C.P., R. D. Green, M.R.C.P., T. St. M. Norris, M.R.C.P., D. W. G. Smith, M.R.C.P., M. I. Toohey, M.R.C.P., C. E. W. Wheaton, M.R.C.P.

Senior physicians, on a salary scale of £1500–£100–£1800 with no emoluments:

J. A. Cardno, M.D., B. Freedman, M.R.C.P., B. Gottlieb, M.R.C.P., P. Harvey, M.R.C.P., Major A. Kahan, M.D., Wing-Commander J. H. G. Mason, M.R.C.P., Lieut.-Colonel H. E. S. Pearson, M.R.C.P.

Surgeon specialists (superintendents), on a salary scale of £1500–£100–£1800 and house valued at £150 a year or allowance in lieu:

W. P. Greenwood, F.R.C.S., R. A. V. Lewys-Lloyd, F.R.C.S., J. M. Milloy, F.R.C.S., J. R. M. Whigham, F.R.C.S. (commencing at £1800); J. E. Piercy, F.R.C.S.E. (commencing at £1500).

Surgeon specialists (deputies to superintendents), on a salary scale of £1500–£100–£1800 with no emoluments and £50 a year as deputy:

H. L. Cochrane, F.R.C.S., G. S. Ferraby, F.R.C.S., J. Gabe, F.R.C.S., J. C. Gillies, F.R.C.S.E., S. W. Holmes, F.R.C.S., I. W. Matheson, F.R.C.S., I. I. Price, F.R.C.S., K. F. D. Waters, F.R.C.S.E.

Surgeon specialists, on a salary scale of £1500–£100–£1800 with no emoluments:

T. J. Eason, F.R.C.S., Major A. N. McCrea, F.R.C.S., H. K. Vernon, F.R.C.S.

Physician superintendents, on a salary scale of £1500–£100–£1800 and house valued at £150:

J. S. Anderson, M.D., J. V. Armstrong, M.D., H. S. Banks, F.R.C.P., N. D. Begg, M.D., F. J. Bentley, F.R.C.P., W. C. Fowler, M.D., J. Watt, M.D. (commencing at £1800); J. C. Blake, M.B., William Gunn, F.R.C.P., W. H. Kelleher, M.D., M. H. Logg, M.D., G. W. Ronaldson, M.D., W. E. Snell, F.R.C.P. (commencing at £1700).

Assistant senior physicians (deputies to physician superintendents), on a salary scale of £1000–£50–£1400 with no emoluments and £50 a year as deputy:

Robert Swyer, M.R.C.S. (commencing at £1300); G. E. Breen, M.D., L. J. M. Laurent, M.R.C.P., J. C. McEntee, M.R.C.P. (commencing at £1250); J. W. Healey, M.D. (commencing at £1200); A. M. Ramsay, M.D. (commencing at £1150); W. J. P. Lillis, L.R.C.P.I., J. J. McCann, M.R.C.P., D. Porter, B.M., W. F. Richards, M.R.C.P. (commencing at £1050).

Assistant surgeon specialist (deputy to medical superintendent), on a salary scale of £1000–£50–£1400 with no emoluments and £50 a year as deputy:

R. Glyn Thomas, F.R.C.S. (commencing at £1150).

As announced last week, Brigadier R. H. Metcalfe, F.R.C.S., and Lieut.-Colonel R. C. F. Catterall, F.R.C.S., have been appointed to the service as surgeon specialists; their salary scale is £1500–£100–£1800 with no emoluments.

---

[1] *Lancet*, 1942, i, 304.

London Association for Hospital Services

Dr. W. Russell Brain has been elected chairman of this association in succession to Sir Bernard Docker, who will continue to serve as a member of the council.

Indian Obstetrical Congress

The fifth All India Obstetric and Gynæcological Congress will be held in Bombay from Dec. 25 to 29 under the presidentship of Sir A. Laxman Swami Mudaliar.

Medical Drawings

For the past year a group of students in the commercial art department of the St. Martin's School of Art (L.C.C.) have been trained in pathological drawing. They have also obtained practical experience by making drawings in operating-theatres of London hospitals. Surgeons or hospitals who may wish to employ them are invited to get in touch with the principal of the school, 109, Charing Cross Road, W.C.2.

Services Award

The North Persian Forces memorial silver medal for 1946 has been awarded to Dr. J. N. McArthur for his article, Malaria Transmission in Borneo, which was published in THE LANCET (1946, ii, 117). The medal is awarded for the best paper on tropical medicine or tropical hygiene published by a medical officer of under twelve years' service in the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or Colonial Medical Service.

Speech Therapy Conference

The College of Speech Therapists is holding a conference in London from Sept. 20 to 24, 1948, when there will be sessions on the following subjects: Aim and Scope of Speech Therapy, Speech Disorders arising from Head Injuries, the Speech Clinic and the Speech Defective Child, and the Rôle of Emotional Problems in Producing Disorders of Speech. It is hoped that during the conference an International Federation of Speech Therapists will be set up again. The conference secretary's address is 68, Queen's Gardens, W.2.

Appointments

BONNIN, J. G., M.B. Melb., F.R.C.S., M.R.C.O.G.: first assistant, orthopædic and accident service, Oldham Royal Infirmary.

CAPLIN, MAXWELL, M.R.C.S.: tuberculosis officer, London Chest Hospital.

CUNLIFFE, A. C., M.A., M.D. Camb: asst. bacteriologist and lecturer in bacteriology, King's College Hospital, London.

DEAN, J. H., B.A., M.B. Camb.: university asst. pathologist, Addenbrooke's Hospital, Cambridge.

DEAN, JOHN, M.B. Camb.: Wander scholar and registrar, Westminster Children's Hospital.

FINLAYSON, A. A., M.B. St. And., F.R.C.S.E.: otorhinolaryngologist, Hospital of St. Cross, Rugby.

JOULES, F. E., M.D. Lond., M.R.C.P.: chief assistant in medicine, Harefield County Hospital, Middlesex.

SUTHERLAND, CATHERINE, M.B. Edin.: asst. M.O., maternity and child-welfare department, Birmingham.

WALSH, BRIDGET, M.B. N.U.I., D.P.H.: medical director, mass-radiography unit, Leeds.

WOOLGROVE, C. G., M.B. Birm., D.P.H.: senior asst. school M.O., Coventry.

Queen Elizabeth Hospital for Children, London:

EVANS, C. F., F.R.C.S., D.L.O.: ear, nose, and throat surgeon.
HARRIS, E. C., M.B. Lond., F.R.C.S.: ear, nose, and throat surgeon
SWAIN, V. A. J., F.R.C.S.: surgeon.

Bristol Eye Hospital:

BARTLETT, C. H., B.A., M.B. Camb., F.R.C.S.: surgical registrar.
WEAR, A. R., M.B. Leeds, D.O.: ophthalmic registrar.

West Bromwich and District General Hospital:

CANT, W. H. P., M.D. Lond., M.R.C.P.: pædiatrician.
WILLIAMS, G. E. O., M.D. Lpool, M.R.C.P.: physician.

London County Council Mental Health Service:

DUNKLEY, E. W., M.B. Lond., D.A., D.C.H., D.P.M.: second asst. M.O., St. Pancras Hospital mental observation unit.

FRYER, G. J. F., M.B.: asst. M.O., St. Bernard's Hospital, Southall.

LANTIN, HAROLD, M.B. Belf.: asst. M.O., Long Grove Hospital, Epsom.

MAY, P. R. A., M.B. Camb., D.P.M.: second asst. M.O., Cane Hill Hospital.

NICHOLSON, BERNARD, M.R.C.S.: asst. M.O., Banstead Hospital, Sutton.

SAINSBURY, PETER, B.A., M.B. Camb., D.P.M.: asst. M.O., Bexley Hospital.

VINCENZI, J. E. G., M.R.C.S.: asst. M.O., Claybury Hospital.

Colonial Service:

ALMOND, ISABELLA, M.B. Sheff.: M.O., Malaya.
EMMERSON, E. N., M.R.C.S., D.T.M. & H.: M.O., Tanganyika.
FERNANDES, H. P., M.R.C.S., D.T.M. & H.: health officer, tuberculosis, British Guiana.
RAM, L. M., M.B. Punjab, M.R.C.P., D.P.H.: M.O., Malaya.
SAMPEY, A. W., M.R.C.S.: M.O., Kenya.
WASE-BAILEY, B. N. V., M.D. Edin., D.T.M. & H., D.P.H.: senior M.O. (health), Sierra Leone.

City of Plymouth Mental Hospital

This hospital, previously known as Blackadon, has bee renamed Moorhaven Hospital. The early treatment unit wi continue to be known as Moorfields Hospital. The post address of both is Ivybridge, South Devon.

Faculty of Homœopathy

On Thursday, Dec. 4, at 5 P.M., at the London Homœopathi Hospital, Great Ormond Street, W.C.1, Mr. Harold Dod will speak on Five Ailments Aggravated by Present Austerit Conditions.

Dr. Arthur Metcalfe, Australian director-general of healt and quarantine, is reported by B.U.P. to be leaving Austral on Dec. 14 for a three-months tour of Britain, Canada, an the United States. He will investigate methods of quarantin in relation to air travel.

CORRIGENDA: *Estimation of renal activity.*—The l sentence of the third paragraph in Mr. Cole's letter last wee (p. 774) should have read: "Where U is the urinary concentr tion, P the plasma concentration, and V the minute-volum of urine, the clearance, represented by UV/P, can remain th same although U rises."

Malaria transmission by blood-transfusion.—The name the correspondent who wrote a letter to the Editor on th subject last week (p. 772) was Dr. K. S. Rodan.

Diary of the Week

NOV. 30 TO DEC. 6

Monday, 1st

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. A. Peacock: Middle Ear and Eustachian Tub
5 P.M. Dr. J. Douglas Robertson: Disordered Metabolism Thyrotoxicosis and Myxœdema.
WESTMINSTER HOSPITAL, Horseferry Road, S.W.1
5 P.M. (Meyerstein lecture theatre.) Clinicopathological demo stration of osteogenic sarcoma.

Tuesday, 2nd

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. H. A. Harris: Anatomy of the Bladder an Prostate.
5 P.M. Prof. G. Payling Wright: Pathology of Primary Tube culous Infection. (First lecture.)
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. R. M. B. MacKenna: Erythema Group of Eruption

Wednesday, 3rd

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Mr. H. F. Lunn: Flexor and Extensor Retinacula Wrist and Ankle.
5 P.M. Prof. Payling Wright: Pathology of Primary and Tube culous Infection. (Last lecture.)
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
2.30 P.M. *History of Medicine.* Dr. E. Ashworth Underwood Charles Creighton (1847–1927)—Scholar, Historian, an Epidemiologist. Prof. M. Greenwood, F.R.S.: Epidem logy of Creighton.
8 P.M. *Surgery.* Sir Gordon Gordon-Taylor, Mr. R. McWhirte Sir Stanford Cade: Carcinoma of the Breast.
SOCIETY OF CHEMICAL INDUSTRY
7 P.M. *Food Group with Society of Public Analysts and oth Analytical Chemists.* (Burlington House, Piccadilly, W.1, Mr. G. E. Forstner, A.R.I.C., Mr. G. W. Monier-William PH.D., Mr. W. F. J. Cuthbertson, A.R.I.C., Mr. N. L. Allpor F.R.I.C., Mr. D. E. Garratt, PH.D.: Occurrence, Physi logical Importance, and Estimation of Metallic Contam nants in Foodstuffs.
ROYAL FACULTY OF PHYSICIANS & SURGEONS, 242, St. Vincen Street, Glasgow
5 P.M. Dr. William Evans: Heart Murmurs. (Finlays lecture.)

Thursday, 4th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. D. V. Davies: *Osteology of the Base of the Skull*
5 P.M. Dr. W. Feldberg: Vasodilatory Nerve Mechanisms.
ROYAL SOCIETY OF MEDICINE
8 P.M. Mr. W. Grey Walter, D.SC.: Electro-encephalogram i Organic *Cerebral Disease.*

TEACHERS OF MEDICINE *

F. M. R. WALSHE
M.D., F.R.S.
PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON; PHYSICIAN IN CHARGE OF THE NEUROLOGICAL DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL

It is fifteen years since Wilfred Trotter stood where I now stand and opened the session of 1932–33 in an address whose ripe wisdom, large humanity, and eloquence remain an inspiration and delight. His title was Art and Science in Medicine, and his theme one that he had adorned on more than one occasion. I shall not seek to challenge comparison with it; but, since the art and science of medicine presuppose the existence and activities of artists and scientists in medicine, let me for a few moments, with such knowledge and sympathy as I can command, consider that particular category of artists and scientists in medicine upon whose shoulders rests the burden—the privilege if you will—of training the medical student.

ORDER AND CHANGE

In the world of the teaching hospital and its school, a little world perhaps, but one that grows very dear to those who like myself have moved in it for more than half a lifetime, teacher and student each occupies his appointed place in that educational plan which is so inadequately subsumed under the title of the curriculum. Over twenty-five years on the active staffs of both undergraduate and postgraduate schools have given me a healthy respect for all three—teacher, student, and curriculum—but equally have left me with few illusions about any of them. For there are times when one's fellow teachers can seem very tiresome, one's students incredibly dumb, and the curriculum a colossal folly. All three, indeed, have come under the heavy fire of criticism in our day, but we must in justice allow that all three have emerged with no mean credit from the major ordeals of our generation.

It is so easy to be critical, particularly of the past; and most easy of course for those who are muddling the present and mortgaging the future. Yet, if the achievements of medicine in our time have been remarkable, as we may fairly claim, then the methods and principles of our predecessors in the teaching of medicine cannot have been altogether futile or misguided. For let us not forget that it is standing on the shoulders of our forbears that we view the fair perspectives of advance that open before us. We are the inheritors of their long and devoted fostering of medical knowledge, and of that academic and practical freedom that they have won for us: freedom we shall do well if we hand on intact to those who follow us.

Of late years medical education has been the theme of long, ardent, and learned debate, and it is not necessary within these walls to recall the major contributions thereto made in their so different fashions by Wilfred Trotter and Thomas Lewis. I am not going to inflict a further chapter of this long and seemingly unending serial story upon you but to sketch in brief outline what I picture as the character and outlook of the ideal teacher of medicine in any adequate scheme of medical education.

I have acknowledged the great debt we owe to our predecessors and have submitted that their labours were not without merit, but this should not be taken to imply that their methods or outlook are incapable of betterment, or are adequate to our educational responsibilities today. Progress necessarily involves change—orderly change. Indeed it has been said that "the art of progress is to preserve order amid change, and to preserve change amid order." For by itself order is not sufficient, and if it is not to degenerate into mere dead repetition it must be continuously infused by novelty. This orderly infusion is progress.

It is because this is so that there is always something interesting to be said about medical education, and it is in the spirit of readiness to accept change, where it is an orderly evolution from what is and has been, that I approach my subject.

WHAT KIND OF DOCTORS?

I know of no better definition of the objects of a teaching hospital than Nathaniel Faxon's, which Professor Himsworth recently brought to my notice—namely, "to advance knowledge, to train doctors, and to set an example of practice." This is no mere abstract proposition, but one that states in unequivocal terms what must be the activities of the teacher and what his purpose.

Of these three items I propose to consider the second one first—namely, "to train doctors." In the words "to train doctors" the one calling first for definition is "doctors," for until we have agreed what these are and should be we can hardly discuss their training.

What a rich and varied pattern of activities the word brings before our minds today: general practitioners, doctors in industry, in the civil, armed, and colonial services of the Crown, medical officers of health, bacteriologists, pathologists, specialists of every variety, medical and surgical, neurologists, and administrators—from the sublime to the less obviously sublime.

How, we may ask, are we to find a common plan of education to meet the needs of so diverse a collection of specialists and experts? Various solutions have been offered to us. Some would solve the problem for us in a sequence of what they would call self-evident propositions—namely, that most doctors become general practitioners, that the general practitioner is the backbone of the profession, and therefore that the scheme of training should be so designed as to concentrate upon his mass-production, leaving all else to postgraduate studies. But those who have done their anatomy will not need to be reminded that there is no more forlorn object of study, no more aimless piece of humanity, than the isolated backbone.

A balanced medical profession must contain every necessary kind of doctor. I shall not embark therefore upon a fruitless discussion as to which field of medical activity is best or most essential. The diversity we now see, a diversity which has very considerably reduced the proportion of general practitioners in the total body of qualified medical men and women, is the natural growth of two factors: the increase and differentiation of relevant knowledge, and the corresponding increase and diversity in the fields of usefulness of the doctor. Therefore, to argue that the general practitioner is more or less important than any other kind of doctor is as futile as to debate whether the comma is more or less useful and important than the semicolon.

Surely, what we need is a common educational plan providing a basis from which all the different specialists we need may ultimately most readily emerge. We must have a less rigid formula than that of a scheme concentrating exclusively upon the training of the general practitioner as we have seen him in the past.

My proposition is then that we need a plan of teaching and a body of teachers of medicine that will best allow the student to develop his bent and find that field of activity best suited to his gifts. For surely it is obvious that no-one really knows, when he embarks upon the study of medicine, to what branch of medical work he is going to feel called, what particular line of study and activity is going to stir his imagination and stimulate his energies.

I had been a medical student for four years before I knew what I wanted to do with my life, and my course was determined when, in 1907, I opened the pages of Sherrington's *Integrative Action of the Nervous System*, which Professor Bayliss had put into my hands. This book, one that later ages will, I firmly believe, acclaim as one of the few imperishable books in the history of medicine and physiology, was no part of the curriculum of the day; and, had my teachers taken the narrow view that nothing should be imparted to me but what was of proven value to the general practitioner as he was then known, I might well have missed one of the most exciting mental experiences of my life, and one which more than any other has coloured and rendered so satisfying to me my years of neurology.

---

* Opening address of the session of the Medical School, University College Hospital, on Sept. 30, 1947.

I ask your pardon for this brief lapse into autobiography—an exercise for which by modern standards I am far too old—but one's experiences are all that one has to offer of one's own, and I choose this one to make my point against any narrowly designed "utility" scheme of training for doctors of the future.

THE TEACHER'S TASK

Now I have promised not to harass you with discussion of the curriculum, but some general ideas as to what is asked of the teacher of medicine must be framed and expressed.

In seeking to do this I cover ground already trodden by Trotter and by Lewis, and can scarcely hope to avoid being an inadequate plagiarist. In brief, the student has to learn certain practical arts, to acquire certain techniques of applied science, to gain familiarity—by handling it—with his material, the human subject well and ill; and to acquire, if he is able, that intuition of reality which in the difficult problems of diagnosis and prognosis will enable him to choose, and to choose correctly, as often as is humanly possible the interpretation to place upon the scattered and incomplete clues that nature may provide. All this comprises what has been called his vocational training.

Knitting all this together and making of it as near an approach to coherent and orderly knowledge as is possible, the student also needs some general ideas and some fundamental definitions. The importance of the latter in logical thought in any field of endeavour cannot be over-emphasised. For example, what confusion we observe in medicine between what is abstract and what concrete, what is an idea and what an event or a thing? Thus, how many of us make it clear to our students that what we speak of as a "disease" is not something concrete that doctors discover, as Columbus discovered America, but is a general notion about like illnesses in different persons? In nature we do not encounter diseases, but only sick persons. Within the covers of a book, which has the depressing title *Influenza*, published some twenty-five years ago in London, there is an illuminating essay, entitled Method and Thought, by the late Dr. F. G. Crookshank, a former student of this school, in which this confusing business of thoughts, words, and things is faithfully and clearly expounded. I earnestly commend its reading to every student whose aspirations rise above a successful and enjoyable trip to that soft-currency area in Queen Square where sits the Conjoint Board.

In the matter of general ideas, too, the student must be given some knowledge of those general laws exemplified by the main modes of functional and structural reaction in disease, as these are seen in symptoms and in objective signs.

Finally, surely it is an ideal always to be aimed at, if but seldom realised, that we should seek to impart to the student a desire—a passion if possible—for understanding what he sees, a desire to know, as far as it may be known, the nature of the phenomena that come under his observation. For it is out of this desire to understand, and from it alone, that can be born the urge to add to knowledge, to break new ground.

EXAMPLE OF PRACTICE

So much for the training of the doctor. We come to another of Faxon's objects: "to set an exampl practice." I take this to include the demonstratio action before the student of the application of wha has learned of art and of applied science—in short, use of judgment and that careful and experie balancing of probabilities that is at the root of medical practice. I should wish it also to include humane outlook on the doctor-patient relationship bids the doctor respect human personality, and see understand it. I have never believed that these th can be taught by precept, nor by hours spent liste to lecturers descanting upon normal and abno psychology. These may, indeed, provide some fr work of ideas, but no more. It is only in our path thr life and in the hard school of experience that this difficult aspect of medicine can be mastered. T are also ethical aspects of practice that I should inc under this heading of Faxon's.

To what ignoble tasks we may today be asked to our skills, the medical and lay press leaves us i doubt: that macabre horror of the sickroom mis euthanasia; and the still more repellent busine artificial insemination employing the anonymous d What in his depravity the body-snatcher was to teaching of anatomy a century ago, so today in med is that furtive and loathsome creature, the anony semen donor, whom some of our profession have c into existence; a fitting symbol of the disintegr of Christian civilisation.

It is not without reason, therefore—though, I too late—that I make a plea for the place of ethi this matter of setting an example of practice.

ADVANCEMENT OF KNOWLEDGE

Finally, and to relieve my listeners from that a embarrassment and discomfort that any mention of et sanctions now evokes, let me return to the first of Fa postulates—namely, the advancement of knowledge.

No-one will dispute that this must occupy a pri place in the activities of any school of medicine, is not to degenerate into a sort of medical polytec Stated in this way the issue is simple, but the adva ment of knowledge implies the presence of research, there are few words around which more misconcep have arisen than this.

In the first place its definition has been some blurred by the halo of sentiment some of its dev have sought to place round it, as though it had s special esoteric quality that no other mode of hu activity possessed; almost, indeed, as though it the analogue, in the world of secular activity, of contemplative life in the world of spiritual activity.

Again, it has come increasingly to be associated our minds with highly organised team activity, o subsidised by large organisations which command budgets. What in the world of commerce is pathetic called the "small man" has his opposite number in t of medicine and science, but we hear less and less ab him, for in any medical school or research institute has been crowded out by the large departments; however brightly there may burn in his soul the to add to knowledge, he will find it hard, if not impossi to get a foothold unless he joins "the big unions."

No-one will deny the intellectual gifts demanded first-class research, or the necessity in medical as other fields of organised large-scale investigation. us not however fall into the vulgar error of suppo that only vast organisations can conduct research, t only the rare genius can add to knowledge, and that independent worker in whom the impulse to do orig research is present cannot labour fruitfully in this fi Discoverers of genius are as rare as poets or painter but this has never deterred the man with the in him from fulfilling himself in verse or on canvas. re the truth is that in medicine most men of intelligence do feel the craving for some adventures ught, the urge to pass the frontiers of the known and hed, and beyond them to chart at least some regions of the unknown, and to throw the light of curiosity upon some dark corner of human ce.

one who puts his observations together to exemplify them some law of nature, to detect some persistent or some ordered recurrence in events, is doing h and seeking to advance knowledge. It is in those who work in clinical medicine in this spirit nature gives the opportunities of new knowledge, e of their intellectual vigilance and preparedness em in the stream of experiences the significant ena and events as these float by.

bmit, therefore, that some infusion of this reasoned ty, some interest in the relation of stubborn facts ral principles, is a vital element in the endowment true teacher of medicine.

us not shrink from the conclusion to which this on, if we accept it, must lead us. It implies he teacher who has not at some time and instinc-, as it were, sought to make some contribution wledge lacks the divine spark and cannot therefore it in his students. Insensibly and inevitably he the descent from the status of educator to that of tructor in techniques.

king back over forty years to my own teachers in hospital and school, they fall naturally in my tion into two categories: those who forced me and gave me something to think about, over bove the factual knowledge they communicated; hose who gave me facts alone. I am grateful to for both were inspired to give the best of what they nd they gave it generously and graciously; but too who it was that influenced me most, who ne the spirit of emulation and the deep desire to some small offering, however modest, upon the of knowledge as I passed by. Such a man was Rose Bradford. Wilfred Trotter was another, was impossible not to be aware of, or not to be ted by, their intellectual distinction. There were too, to whom the debt of my generation in this was great; all were alike in that they were men their time had broken new ground in medicine and richer than it had been before their day.

spirit of inquiry, therefore, is *the* vitalising element life of a medical school. It can flow only from achers; and whether these are academic teachers in large-scale organised experiment, or inde-t workers following their problems as opportunity t, and perhaps also engaging in the private practice cine, does not seem to me to matter greatly. *spirit that counts*, the interest in new observation, apacity for the steady contemplation of facts, of generalising from them, and an unwillingness pompously and incuriously through life along rmanent way of established arts and techniques.

THE TEACHERS

brings me to my last consideration. An anti-has been made, in discussion on medical education, n theoretical and vocational teaching. That this real distinction in thought and in the method of g is apparent. Yet how disastrous it would if teachers were to allow themselves to lapse into or other category of teaching exclusively; if, for ple, the teacher of the practical arts and techniques to content himself with this and felt no obligation etrate to fundamentals, to view medicine philo-ally or as a body of knowledge in which coherence was to be sought; or, on the other hand, if the teacher of theoretical medicine lived in a world of principles and of abstract ideas about disease and ceased to be actively interested in practical arts and techniques, in the intellectual aptitudes developed by diagnosis and prognosis in individual cases, or in the humane side of medicine in which the doctor faces and seeks to understand the personality and the human needs of his patient.

Thomas Lewis clearly foresaw such a danger and warned against it; but it is clear that the presence in the modern medical school of two categories of teacher, the practising consultant and the salaried academic teacher, opens the door to this disastrous dichotomy. The practising teacher is familiar in his everyday work with the individual seen against the backgrounds of his home, his family, and his work. The full tide of human needs and distresses bears down daily upon him, and the arts and techniques of medicine are his constant and exhausting preoccupation. He may cease to look beyond them.

For the cloistered academic teacher life is different. He gets his patients washed and tidied and laid out in rows in hospital wards; their importunate and exacting wives and mothers-in-law do not intrude upon his profound cogitations. No unpleasant smells or noises break in on his ordered eloquence; house-physicians and nurses wait on his bidding and tremble at his voice, and all those seeming irrelevances that are so necessary to the balanced comprehension of the patient's total situation are carefully tidied away out of his sight. He does not miss them, for he has never known them. He is rather like the florist who can arrange the plucked blooms, from which the dead leaves and the dirty roots have been removed and the earwigs shaken off, into all the combinations of form and colour his fancy dictates.

I feel sure our clinical professors will greet this simple and faithful picture of their austere lives with sentiments of happy recognition.

The practising teacher, on the other hand, is the toil-worn gardener, who has to bend his proud back and soil his hands; but his reward is that he does know the plant as a structural and functional unity, and knows too something of the soil and the floral community in which it has grown and lived. Would it be surprising, therefore, if the former became the somwhat dryly theoretical teacher and the latter a rather pedestrian vocationalist?

We dare not, therefore, separate these two aspects of teaching. Each one of us must seek to be the artist, the man of science, and the humanist of Trotter's imagination and of his example.

Finally, it is not amiss to say that every teacher is the better for knowing how to teach. Oddly enough, the university grade of teacher receives no training in the pedagogic art and has to teach by the light, often intermittent and smoky, of nature.

CONCLUSION

You have listened very patiently while I have been building castles in Spain; you have had to bear with the painful reality depicting the unattained ideal. The cynics among you, however, and they must be many in this disillusioned age, must have found some satisfaction in the sad contrast, and therefore I need not apologise.

But my situation also has not been without its charms; for, as my argument has rocked to and fro, somewhat alarmingly at times I fear, swaying now to one point of view and now to another and contrary one, I have had the opportunity of noting the play of conflicting emotions in the more informed and critical of my audience. But I have sought to give everyone the satisfaction, and I know of few greater, of hearing something from which he could heartily and angrily dissent, and I trust something also to which he could scarcely refuse to agree. What could be fairer or more exasperating?

was determined when, in 1907, I opened the pages of Sherrington's *Integrative Action of the Nervous System*, which Professor Bayliss had put into my hands. This book, one that later ages will, I firmly believe, acclaim as one of the few imperishable books in the history of medicine and physiology, was no part of the curriculum of the day; and, had my teachers taken the narrow view that nothing should be imparted to me but what was of proven value to the general practitioner as he was then known, I might well have missed one of the most exciting mental experiences of my life, and one which more than any other has coloured and rendered so satisfying to me my years of neurology.

I ask your pardon for this brief lapse into autobiography—an exercise for which by modern standards I am far too old—but one's experiences are all that one has to offer of one's own, and I choose this one to make my point against any narrowly designed "utility" scheme of training for doctors of the future.

THE TEACHER'S TASK

Now I have promised not to harass you with discussion of the curriculum, but some general ideas as to what is asked of the teacher of medicine must be framed and expressed.

In seeking to do this I cover ground already trodden by Trotter and by Lewis, and can scarcely hope to avoid being an inadequate plagiarist. In brief, the student has to learn certain practical arts, to acquire certain techniques of applied science, to gain familiarity—by handling it—with his material, the human subject well and ill; and to acquire, if he is able, that intuition of reality which in the difficult problems of diagnosis and prognosis will enable him to choose, and to choose correctly, as often as is humanly possible the interpretation to place upon the scattered and incomplete clues that nature may provide. All this comprises what has been called his vocational training.

Knitting all this together and making of it as near an approach to coherent and orderly knowledge as is possible, the student also needs some general ideas and some fundamental definitions. The importance of the latter in logical thought in any field of endeavour cannot be over-emphasised. For example, what confusion we observe in medicine between what is abstract and what concrete, what is an idea and what an event or a thing! Thus, how many of us make it clear to our students that what we speak of as a "disease" is not something concrete that doctors discover, as Columbus discovered America, but is a general notion about like illnesses in different persons? In nature we do not encounter diseases, but only sick persons. Within the covers of a book, which has the depressing title *Influenza*, published some twenty-five years ago in London, there is an illuminating essay, entitled Method and Thought, by the late Dr. F. G. Crookshank, a former student of this school, in which this confusing business of thoughts, words, and things is faithfully and clearly expounded. I earnestly commend its reading to every student whose aspirations rise above a successful and enjoyable trip to that soft-currency area in Queen Square where sits the Conjoint Board.

In the matter of general ideas, too, the student must be given some knowledge of those general laws exemplified by the main modes of functional and structural reaction in disease, as these are seen in symptoms and in objective signs.

Finally, surely it is an ideal always to be aimed at, if but seldom realised, that we should seek to impart to the student a desire—a passion if possible—for understanding what he sees, a desire to know, as far as it may be known, the nature of the phenomena that come under his observation. For it is out of this desire to understand; and from *it alone*, that can be born the urge to add to knowledge, to break new ground.

EXAMPLE OF PRACTICE

So much for the training of the doctor. We con to another of Faxon's objects: "to set an exam practice." I take this to include the demonstrat action before the student of the application of w has learned of art and of applied science—in sho use of judgment and that careful and exper balancing of probabilities that is at the root o medical practice. I should wish it also to includ humane *outlook on the doctor-patient* relationshi bids the doctor respect human personality, and s understand it. I have never believed that these can be taught by precept, nor by hours spent li to lecturers descanting upon normal and ab psychology. These may, indeed, provide some work of ideas, but no more. It is only in our path t life and in the hard school of experience that thi difficult aspect of medicine can be mastered. are also ethical aspects of practice that I should i under this heading of Faxon's.

To what ignoble tasks we may today be asked t our skills, the medical and lay press leaves us doubt: that macabre horror of the sickroom mi euthanasia; and the still more repellent busin artificial insemination employing the anonymous What in his depravity the body-snatcher was t teaching of anatomy a century ago, so today in me is that furtive and loathsome creature, the anon semen donor, whom some of our profession have into existence; a fitting symbol of the *disinteg* of Christian civilisation.

It is not without reason, therefore—though, I *too late—that I make a plea for the* place of eth this matter of setting an example of practice.

ADVANCEMENT OF KNOWLEDGE

Finally, and to relieve my listeners from that embarrassment and discomfort that any mention of e sanctions now evokes, let me return to the first of Fa postulates—namely, the advancement of knowledge

No-one will dispute that this must occupy a pr place in the activities of any school of medicine, *is not to* degenerate into a sort of medical polyte Stated in this way the issue is simple, but the adv ment of knowledge implies the presence of research there are few words around which more misconce have arisen than this.

In the first place its definition has been some blurred by the halo of sentiment some of its dev have sought to place round it, *as though it* had special esoteric quality that no other mode of h activity possessed; almost, indeed, as though it *the analogue*, in the world of secular activity, o contemplative life in the world of spiritual activity.

Again, it has come increasingly to be associate our minds with highly organised team activity, subsidised by large organisations which command budgets. What in the world of commerce is patheti called the "small man" has his opposite number in of medicine and science, but we hear less and less a him, for in any medical school or research institut has been crowded out by *the large* departments; however brightly there may burn in his soul the to add to knowledge, he will find it hard, if not impos to get a foothold unless he joins "the big unions."

No-one will deny the intellectual gifts demande first-class research, or the necessity *in* medical other fields of organised large-scale investigation. us not however fall into the vulgar error of supp *that only* vast organisations can conduct research, only the rare genius can add to knowledge, and that independent worker in whom the impulse to do ori research is present cannot labour fruitfully in this Discoverers of genius are *as* rare *as poets* or painte mercial travellers and salesmen. They responded well than the professions and the housewives (H), o showed by far the best results. Clerical workers (C) luded secretaries, typists, &c., mainly young women. iong the skilled workers (S) were 3 mechanics, 1 miner, oiner, 1 tailor, 1 shepherd, and 1 foreman on a farm. unskilled (US) we listed domestic and factory workers, op assistants, message boys, &c. Students, school-ildren, and apprentices were included in the training oup (T); 2 of these continue their studies, 2 work domestic and labourer, 1 as secretary, and 4 are in eltered occupations (SO)—i.e., working on the farm in the house or business of their relations, assisting t not in a capacity justifying the award of a regular age. Unemployed (U) refers to temporary unemploy-ent after the patient had taken up work after discharge om hospital. Those classified as idle (I) had never tempted to work regularly. Among this group we found patients who should be readmitted to hospital.

MBERS OF PATIENTS IN DIFFERENT OCCUPATIONS BEFORE ILLNESS AND AT FOLLOW-UP

Before illness	At follow-up										
	P	B	H	C	S	US	T	R	SO	U	I
P 7	6	..	..	..	..	..	..	1	..	..	..
B 10	..	3	..	..	..	1	..	1	3	..	2
H 12	..	..	10	..	..	..	..	..	1	..	1
C 10	..	..	..	3	..	..	..	..	2	3	2
S 8	..	..	..	..	4	..	..	..	2	1	1
US 11	..	..	..	..	..	6	1	..	2	1	1
T 10	..	..	..	..	1	2	2	..	4	..	1
tal 68	6	3	10	3	5	9	3	2	14	5	8

ore than half the patients could earn their living, d more than three-quarters were usefully employed. ore than half the patients had the same occupations before their illness, or similar ones, the other half ving gone down on the occupational scale. In view of e length of their illness and of their absence from me and the labour market, and the relatively young e of some at the outset of their illness, these figures e very satisfactory.

We also found that there was a greater tendency to eterioration, as regards occupation, in the schizo-hrenics than in the non-schizophrenics, which is what ne would expect.

Of 31 statements made by relations about the quality of the patient's work 18 said they worked well, 11 escribed the work as poor or deteriorated, and 2 men-tioned recent improvement. On the other hand, 9 out of 10 patients emphasised how well they worked, and one said that they found it difficult to take up work ain. Some patients lacked judgment about their ilities, and it is reasonable to suspect that professional andards were often reduced or lost, as the following amples suggest:

> patient described himself as a salesman and supervisor is father's firm, but his father wrote: "I am sorry he not found a useful occupation yet; being the son of the ctor he wanted to be appointed to a managerial post which cannot possibly undertake. He travels to the city about e days weekly and is helping in the business for about hour, when he will go off for coffee, return for a little while, go for lunch, returning usually to his home in the early noon."

> nother patient worked as a finisher in a dress factory. employer reported: "Her work is most unsatisfactory, , and inaccurate. Whenever a remark is made on this ount, she is most offensive and will say 'You can dismiss f you don't like it.' She is most uncritical towards her evements and does not try to do better."

> mployer's report on a librarian-secretary: "Patient was sed because she was considered incapable of doing job. The informant would show patient how to do a certain job. She might do this correctly once or twice, but would then lapse back into her own way of doing it and forget all the things he had told her. Informant added that she thought she knew all there was to know about library work. She would not be taught. She was always perfectly satisfied with what she had done and never asked for help."

In 8 cases we heard about the patients' initial difficulty in being in time for work and appointments but also that this difficulty, prominent in the first year, had disappeared later.

In 7 cases the relations complained about lack of discrimination in money matters: "She denies herself over pennies, giving generous presents or taking expensive holidays. . . ."; "Before, the patient would say 'We can't really afford that.' He never has said so since the operation." On the other hand, the majority seemed to manage their money matters well. Even when gambling and betting were mentioned, they were done only on a small scale.

An interesting feature is the frequent change of jobs: 11 patients had had more than two jobs, some up to five, since their discharge. This may be partially due to dismissal because of inefficiency, but the patients did not take this view:

> A motor mechanic wrote a year after leaving hospital: "I have got on well since I left. I have been doing nursery work and find it interesting. Before this I worked as a gardener at a hospital here, as a mechanic, also as a sheet-metal worker under a friend of mine, and as a farm labourer."

One is inclined to blame the restlessness apparent in other fields of behaviour for some of these changes. This is supported by the frequency with which younger patients wrote of plans to emigrate.

Interests and Hobbies

In their hobbies and interests we found signs of the same restlessness. Of 18 patients 17 reported that their interests were the same as before their illness, but 10 of 22 relations reported that the patient's interest had changed. Most remarkable, however, were the diversity and multiplicity of hobbies and interests in one patient:

> "I still have my large flights full of birds. I have 40 canaries, also budgerigars and British birds. I keep them mostly for shows. Also I read a lot of books. I have my four hives of bees to look after as well. And I still have my music practice, as I have played a piano accordion for three years now."

To this list his sister added:

> "He has many hobbies, wireless. . . . He also has a few ducks which he hopes to sell at Christmas. He goes to the picture hall, also goes two or sometimes three nights a week to play darts and dominoes from eight to ten. He likes country walks too and takes our dog for a stroll every evening. As soon as he is finished at the shop and had his tea he is away into his tool-shed doing all kinds of jobs."

This is perhaps an extreme case, but many of the same sort could be quoted from our material.

Most of the patients preferred sports and light entertainment. Outings of various sorts were in great favour, 18 relations and 16 patients reporting that they "enjoy going places."

> "She is taking dancing-lessons, practises the piano every day, embroiders her Christmas presents, goes to celebrity concerts, and is determined, as she says, 'not to miss anything.' She keeps an engagement book, as she does not want her dates to clash."

It is probably not accidental that sports and light entertainment played such a large part in the letters of relations and patients, many of whom had formerly serious interests in art, literature, religion, or politics. One patient wrote:

> "A great many strong opinions that I used to have seem to have disappeared altogether. I had, in spite of certain

Yet behind the angularities and imperfections of my address there does rest with me the profound conviction that the responsibilities of the teacher of medicine have never been heavier than now, nor his opportunities greater; and each of us must bear constantly in mind that it is his individual duty to advance knowledge, to set an example of practice, and so to train doctors that there will always be among our pupils those whom we have *inspired and fitted to bring these ideals nearer to* realisation than we have done.

Let there be no mistake; if we accept narrower aims than these, our medical schools will sink to the dead level of polytechnics, and the torch of living and growing medicine will pass from our hands to separate research institutes, to which all that is best in the coming generation of potential teachers and investigators will turn, and the prestige of the medical school and teaching hospital as we have known them will have departed for ever.

PERSONALITY CHANGE AFTER PREFRONTAL LEUCOTOMY

L. Frankl
Ph.D. Vienna, M.B. Lond.
ASSISTANT PHYSICIAN

W. Mayer-Gross
M.D. Heidelberg, M R C.P.
DIRECTOR OF CLINICAL RESEARCH

CRICHTON ROYAL, DUMFRIES

Reporting on the immediate results of prefrontal leucotomy performed in Crichton Royal, Berliner et al. (1945) and Moore (1946) pointed out that closer studies of the postoperative personality changes would be necessary, especially before leucotomy could be recommended in recent mental illness. The same was suggested by the Board of Control (1946) in a pamphlet which surveys 1000 cases operated on in British hospitals up to 1945. This number shows to what extent the treatment has been applied and no doubt is still being applied in this country. About a third of the patients collected in the pamphlet have been discharged from hospital, but little has so far been published about their lives in the family and community; follow-up studies are obviously needed.

An ideal study of this kind should assess the patient's prepsychotic personality, follow the changes due to his illness up to the operation, and compare them with the postoperative changes. Since improvement may take place as late as two years after the operation, the follow-up should cover at least two years. Even necropsy findings should be included, in view of the different positions of the cut in the brain reported by Meyer and Beck (1945).

In the present investigation the patients who responded most successfully to the treatment—i.e., those who were discharged to their homes—were specially studied. The disadvantage of the relatively small numbers of cases available from one hospital is counterbalanced by selection and diagnosis by the same team of physicians, standard operative procedure and postoperative treatment, rehabilitation in the same surroundings, and discharge according to the same principles.

MATERIAL

Of the first 170 patients operated on between February, 1943, and June, 1946, 77 were discharged from hospital; 9 had to be readmitted after being at home from two to twenty months. The remaining 68 patients were 28 men and 40 women. In our total of operated patients the number of males and females was almost equal. The sex-distribution is at variance with the larger material of the Board of Control (1946), which shows a higher proportion of men successfully treated; but one would expect women to be taken out of hospital more easily than men after a long illness. Of our patients 14 had lived at home more than two years, 28 between one and two years, and 26 less than a year.

Three-quarters of the cases were long-standing scl phrenia of the catatonic and paranoid types; 9 obsessional neurosis, 7 melancholia, and one recur mania; 9 patients had been ill less than three years, remainder longer; 18 had been ill more than ten ye

In cases with a duration of illness less than three y the less drastic methods of treatment, including trically induced convulsions and insulin coma, had *tried without success, and there was no reasonable h* of spontaneous remission. Before the operation patients had been in hospital from one to five ye and 12 for more than five years; 11 patients were oper on within the first year of their stay in hospital, but had been invalids at home for many years. The len of stay in hospital after leucotomy was three mo in 7 cases, from three to nine months in 51, and over months in 10.

METHOD

Since the patients came from all parts of the Bri Isles, a personal follow-up of all cases was impractical but many discharged patients and their relations tinued to correspond with us. We therefore attemp a follow-up by letter, well aware of the shortcoming this method. We saw 8 patients personally; this gr served to check the information obtained from letters. They were either within easy reach for interview or visited the hospital from time to ti thus providing an almost complete picture of th progress. They were representative of the whole se as regards diagnosis (6 cases of schizophrenia, 1 melancholia, and 1 of obsessional illness) and as rega the length of time since discharge.

In view of the suggestibility of any lay person on efficacy of medical treatment and cure, we did not *a questionnaire but sent a letter of general* inqui The questions dealt only with the patient's prevaili mood, his occupation, and social behaviour. The let was first addressed to the patients; later a simi letter was sent to the relations.

The method used for assessing the replies was develop by Mr. J. Raven, director of psychological research the hospital. After the replies had been classifi according to whether they were patients' or relatio descriptions each statement was tabulated in such a w that the frequency of any item could be read vertical while a horizontal reading gave a brief picture of ea patient. The drawback is that the table only gives t frequency of the statements, which is not necessar the same as that of the items mentioned. The meth therefore resembles more that of a historian rec structing a past age from contemporary letters than th of an observer counting facts.

RESULTS

Nearly all the patients replied; no patient seem to resent the inquiry. In a few cases the relations wit held our letter from the patient, being afraid of remindi him of the operation. Most patients' letters were sho and simple, some even childish in style, though mo of the patients had been well educated and accustom to writing. The simplicity of the patients' letters w *striking* when compared with the full and elabora descriptions received from their relations. How comple was this written information from the relations is show by the fact that, when the letters were compared with t results obtained by interviewing *the patients*, there w conformity on all important points.

Work and Occupation

The *working capacity* of these patients, who witho operation would have been chronic invalids, is shown the accompanying table. Among the professions were 1 lecturer, 3 teachers, 2 nurses, and 1 barrist the last *now living in retirement*. The business group included independent owners of businesses as well reflection of the moral standards of the middle-class group from which our patients were drawn, and of the constant care they received in their homes after discharge.

Physiognomy

A changed physiognomy was often reported. This referred not only to the common increase in weight or to greater care in dress, &c., but also to a greater freedom in demeanour and bearing. The patients emphasised their feeling of good health and well-being, their splendid appetite, and their sound sleep. Only 1 patient complained of insomnia. The ravenous appetite slowly subsided in time; none of our patients discharged for more than a year showed this symptom. Similarly the excess in weight disappeared after some months or years.

Mood

Most striking to the eye, and reported in 63 letters, were the patient's visible happiness and all-pervading cheerfulness:

> "Her outstanding qualities now are her gaiety of spirits, her energy and love of life."
>
> "She has been happier and more contented than I have known her for the last twenty years."
>
> "I find after all the world a nice place to be in."

Only in 2 cases did we hear that the patient was temporarily unhappy.

The patients had no doubt about their success in life after their return home. Increased self-esteem and lack of self-criticism were only too obvious both in letters and in interviews. They cared little for what others thought or said and were convinced that what ey did was right. One can easily realise that the people und them tended to minimise or even to suppress less easant features, seeing the patient so happy and pleased th himself.

COMMENT

From these data it is possible to sketch the character a patient after leucotomy.

The patient is physically healthy, a good eater and eeper, with considerable euphoria. His prevailing ood is cheerfulness; he does not worry, is happy and ntented, and shows it. He has a high opinion of himself d his abilities. He may take his responsibilities too sily or may shirk them altogether. He leads an active fe, is restless, and likes movement and change. His terests and hobbies are varied and variable, with a reference for light entertainment and superficial astimes. He is easy-going, a good mixer, and fond of cial life and of being on good terms with everybody.

On the other hand, his relations with the people round im are often without depth of feeling. He shows little ympathy or consideration for his next of kin or anybody lse. He neither regrets nor repents for whatever he may ave done or said. He may be self-willed, headstrong, and nable to see the other person's point of view. He tends o quickly passing outbursts of temper. He may attend o his work as before or may do less well, but he invariably hinks he does well; he is not a perfectionist.

This picture is, in any particular case, modifiable y special features traceable to the personality before peration. Positive symptoms of the former psychosis, delusions, hallucinations, obsessional ideas, and rituals were mentioned in some letters but seemed on the whole to be insignificant. Of the 14 letters mentioning persisting symptoms 8 were from obsessionals and their relations. In almost every instance the number of obsessions and rituals had diminished. Guilt feelings and anxiety had disappeared. The obsessional ideas had lost their predominant influence on the patient's behaviour.

It may be objected that hyperactivity, shallowness of affect, impulsiveness, and lack of judgment are symptoms of the schizophrenic illness from which three-quarters of our patients suffered, and that even if they exist as a background to the cheerful, outgoing, and sociable personality as described—which is certainly not schizophrenic—they are nevertheless remaining symptoms of the illness. A comparison of the frequency of these traits in schizophrenics and non-schizophrenics shows that the 17 manic-depressive and obsessional patients contributed in the same proportion as the schizophrenics to these traits as they did to all the principal features from which the composite picture was developed.

DISCUSSION

In clinical terms the main features of this composite picture are symptoms of frontal-lobe damage after head injury (Feuchtwanger 1923) or lobectomy for tumour (Rylander 1939) in man, and after experimental removal of the area in primates (Fulton 1943). In the emotional field are euphoria, fatuous equanimity, absence of finer emotional response, rudeness, and tactlessness. In the motor field are hyperkinesis, restlessness, and distractibility. In thinking there are turning towards the "concrete" (Goldstein and Scheerer 1941), impairment of "synthesis" (Brickner 1936), and lack of insight (Guttmann 1931). These symptoms may be much milder after leucotomy than after gross cerebral injuries; but the difference is only one of degree. Immediately after the operation we find other frontal deficiency signs—ravenous appetite, disturbance of memory and retention, apathy and laziness, irritability, and lack of emotional inhibition; symptoms which seem to disappear in time and under proper rehabilitation.

From this analogy it follows, and is suggested as a theory of the treatment, that the operation, if successful, provides the patient with a new framework of personality caused by the isolation of his prefrontal areas. If the post-leucotomy patient's mental life has to be reconstructed within a new framework, one can hardly expect this to be accomplished in a few weeks or months. In 31 letters it was mentioned spontaneously that the patients were still improving, some of them two years after the operation. Neurosurgeons know of the slowness of adaptation when larger parts of the brain have had to be removed; one also remembers the time-consuming work of the head-injury institutes and special schools after the 1914–18 war in which penetrating injuries of the head were so common.

In the light of our theory the original prepsychotic personality should not have a decisive influence on the final result. Unfortunately our material does not allow a definite answer on this point. There was often only scanty information about the patient before his psychosis which had begun many years previously. But some of our patients who had been abnormal since adolescence have done unexpectedly well though they had not matured before illness to anything that could be called an adult personality.

The following practical conclusions can therefore be drawn.

(1) *Selection of Cases*

Hebephrenics showing only lack of initiative, affective blunting, and facetiousness are too akin to the frontal syndrome to permit any improvement after operation. After a few disappointing results, we, like many other workers, have given up considering the treatment in this kind of case.

In severe obsessional illness crippling the patient's life for years leucotomy seems the only way out of chronic invalidism and admission to hospital. Thus, 11 patients severely handicapped by their illness, some after years of unsuccessful psychotherapy, have been operated on and returned home or are ready for discharge.

In chronic affective psychoses periodicity has been abolished and more than three-quarters of the patients have recovered; but our number in this group is small.

intelligent doubts, great religious faith, but now I seem to have no enthusiasm for any kind of religion."

Similar observations were reported by Hutton (1947).

Where old interests were kept up there were sometimes signs of a lowering of standards in taste or cultural level: "His former love for music has not returned." Poetry was hardly mentioned; reading mainly referred to factual matters. A mother wrote: "She is not yet able to read the heavier type of books she used to read." On the other hand, one of our younger patients showed a remarkable talent for original drawing which, according to her mother's letter, was well maintained after the operation; she continued to attend the art school with much zeal.

Social Life

In contrast to the reserve and withdrawal during the illness, the patients, after operation, took a definite part in the social life of the community: 22 relations' and 11 patients' letters mentioned that they were sociable. Many were described as popular, taking part in all social events, helping in clubs and societies, being friendly with everybody, and liking to entertain. Social activity seemed often to be an outlet for the patient's restless drive.

"She had a party the other evening and entertained her friends. She played the piano, played duets, games, &c., and it reminded me of similar evenings many years ago. Maud's friends think that a miracle has happened. She is like the person she was before she became ill—except that she is a much happier edition. A favourite phrase is 'I laughed and laughed' as she relates some joke."

"He takes part in all the social events in the neighbourhood, goes to dances, to the cinema, whist drives, or invites people to the house for cards. He has won quite a number of prizes at whist drives and also puts small sums of money on horses."

On the other hand, individual personal friendship was hardly mentioned in the letters. When we put this question to the interviewed patients and their relations, we received rather characteristic answers: "She has not made any new friends"; "Nobody would be bothered with her"; "Nobody would make a pal of her, she considers herself first always"; "She is not a person you could either like or dislike. She is completely colourless"; "There is a kind of vacancy about her."

Family Life

Shortcomings of this kind would be expected to be more obvious in the family life of our former patients: 48 letters commented on the patients' behaviour towards their relations, all patients contending that they got on very well. However, 10 out of 29 relations found it difficult to live with the patient. Three main reasons were given for this difficulty: (1) shallowness of feeling and lack of affection and of consideration for others, even for children; (2) domineering manner, self-willed stubbornness, and inaccessibility to reason; and (3) outbursts of temper and irritability.

Lack of affection was especially distressing to people who had shown the utmost consideration for the patient returning after a long absence. They found that the patient accepted it without any appreciation as a matter of course. Wives and children felt the emotional estrangement and indifference, and suffered under it.

"He is not like his old self; for instance he does not take the interest he should in our little girl, aged 3 years. He doesn't play with her like other fathers."

"He seems very shallow in his feelings and incapable of affection. He cares for no-one but himself."

"Kitty, our daughter, greeted her mother's return with enthusiasm; but, so far as I could see, her mother eventually killed Kitty's enthusiasm for her companionship. After spending the Easter holidays with her, Kitty wrote to her house-mistress asking for permission to return to school a day earlier with the new girls and wrote that she had n been so miserable in her life."

Stubbornness and inability to see another's p were considered by some relations to be a return the patient's behaviour in adolescence; by othe completely new trait:

"She used to be quite the opposite."

"Her domineering manner, maintenance of her opinion, &c., make her a difficult person to get on One got the impression that the domineering and diff character of her youth was accentuated."

"She was always adventurous, difficult to advise, somewhat self-willed. Now she is quite unaware of obst to what she wants to do . . . they don't exist, and her is completely closed to advice or suggestion; she speak such advice in an impersonal way, as if it does not con itself in her mind with her actions."

"There is one thing, she is never repentant in any when she has done any wrong."

"Everything she says and does is right in her own m Always it is my daughter and I that are in the wrong."

Outbursts of temper were the least disturbing, bec the 13 letters recording it also noted how short-lived t were. Irritable excited scenes "seem to pass im diately, and she is at once as though nothing unu had occurred." Improvement of irritable react with the passing of time since the operation mentioned in several letters:

"I was apt, after my return home, to allow my ten to get the better of me."

"He sometimes loses his temper over a mere trifle (often) and gets excited, but I notice if I take no heed of it passes over soon, in a few seconds, maybe; he is not b tempered afterwards, but his usual self again."

The changed emotional behaviour was, however, always considered disturbing in the family gro Some relations saw its positive value: 15 wrote t the patient never worried, not even in grave situatio

"Obstacles seem not to exist if he wants something, he takes good care that he gets it. Everything he does is ri in his own mind; he is never repentant nor shows sign regret."

"She never in the past worried much, but now she definitely free from any worry. This is the most mar difference in her condition. In fact, occurrences or po bilities which would be expected to alarm her hardly app to affect her at all. For instance, early this year my daugh caught anterior poliomyelitis, but I do not think my w realised the danger."

"The patient is so far from worrying that he seems treat without much gravity really serious circumstanc He behaved with his usual calm during a rather unpleas miscarriage I had in the spring, and attended his badmint club, the cinema, and a fishing excursion just as usual."

Sex and Married Life

After leucotomy there was little indication of ir sponsible behaviour among our cases. This is remarkal in view of their relatively young age, 26 being und thirty and 20 under forty at the time of dischar Three-quarters of our patients were single—24 men a 27 women. In 1 man only was excessive sexual indulgen reported. This being an entirely new trait, it great shocked his respectable family. In none of the unmarri women was there any evidence of sexual promiscuity 2 men were reported to be considering marriage; 1 h married much against the desire of his family. Of t 2 married women under forty-five in our material o was expecting a child. The wives of 2 of the 4 marri men had become pregnant since the patient's retu home, one of them for the second time.

Finally, there was no report of any serious confli with law and order. This important negative findin together with the restraint in sexual matters, may be

THERAPEUTIC ABORTION

BY MEANS OF SOFT-SOAP PASTES

H. H. Fouracre Barns
M.B. Lond., F.R.C.S., M.R.C.O.G.
[illegible] ASSISTANT IN THE OBSTETRIC UNIT, UNIVERSITY COLLEGE HOSPITAL; CHIEF ASSISTANT, DEPARTMENT OF OBSTETRICS AND GYNÆCOLOGY, ST. THOMAS'S HOSPITAL; GYNÆCOLOGICAL SURGEON, HOSPITAL FOR WOMEN, SOHO SQUARE

SEVERAL German writers in the 'thirties reported on the dangers of introducing soft-soap pastes into the uterus to terminate pregnancy. More recently Weilerstein (1944) in America has drawn attention to these dangers, adding that he understands that the method is ineffective in half the cases. On the other hand Doderlein, quoted by Riddell ([illegible]), said that he had used such a paste on 35 occasions and had been more than satisfied with the results.

In this country attention has been drawn to this method by Browne (1946) and Barnes (1946). While in no way wishing to minimise its risks, I believe it to be justified when carried out under ideal surgical conditions by experienced gynæcologists.

The original pastes used on the Continent were named 'Interruptin' and 'Provocol.' Provocol contains, in slightly different proportions, the same ingredients as does the '[illegible]us' paste, used at University College Hospital in 1939. It consists of olive oil 32%, cocoa butter 2·66%, caustic potash 4·8%, caustic soda 1·86%, thymol 0·07%, tincture of [illegible] 2·66%, benzoic acid 1·33%, metallic iodine 0·66%, potassium iodide 2·0%, and distilled water 51·96%. The paste we now employ is: stearic acid 10%, arachis oil 20%, [illegible] solution (consisting of potassium hydroxide 9·5 parts, sodium hydroxide 3·75 parts, and water to 100 parts) 20%, 'Lanette wax SX' 1·5%, chlorocresol 0·05%, and water to 100%. The paste is sterilised in the autoclave.

TECHNIQUE

The patient is admitted to hospital and prepared for vaginal operation. Premedication with 'Omnopon' gr. $^1/_3$ and scopolamine gr. $^1/_{150}$ is given an hour before the operation.

The patient is taken to the theatre and placed in lithotomy position. Anæsthesia is not needed. The vulva and vagina are cleaned with a solution of 'Dettol,' and sterile towels are applied. Bimanual examination is made to confirm diagnosis and to determine the position of the uterus. The cervix is exposed and grasped with a pair of sponge-holding forceps and again painted with dettol solution. The sterile paste, previously warmed to 100°F, is injected into the lower part of the uterine cavity using a 20 ml. syringe and a Forsdike's intra-uterine tube. The tube is inserted just through the internal os of the cervix, care being taken to avoid touching the vaginal walls with the tube during its introduction, and the paste is injected very slowly and without any force, about a minute being taken to inject each 5 ml. The tube is withdrawn, and the cervix is inspected to see that the paste does not return.

TABLE I—INDICATIONS FOR THE TERMINATION OF PREGNANCY

Indication	Duration of pregnancy (weeks)				Total no. of cases
	12 or less	13–16	17–20	More than 20	
Pulmonary lesions:					
Pulmonary tuberculosis ..	20	7	0	2	29
Bronchiectasis	0	0	0	1	1
Chronic bronchitis and asthma	0	0	0	1	1
Cardiovascular lesions:					
Valvular disease	5	9	0	1	15
Hypertension	0	1	0	0	1
Thyrotoxicosis	1	1	0	0	2
Psychiatric conditions:					
Mental instability	6	4	2	3	15
Renal lesions:					
Recent nephrectomy ..	1	0	0	0	1
Renal calculi	1	1	0	0	2
Chronic nephritis	0	1	0	0	1
Chronic pyelitis	1	0	0	0	1
Miscellaneous lesions:					
Recent radical mastectomy for carcinoma	1	0	0	0	1
Bilateral congenital dislocation of hips	1	0	0	0	1
Total	37	24	2	8	71

The amount of paste injected has varied with the operator and the duration of the pregnancy. As a working rule it is suggested that the amount should be 5 ml. plus 1 ml. for each week of pregnancy.

A few hours after the operation the patient is given 1 or 2 oz. of castor oil.

RESULTS

Table I shows that in the present series of 71 cases in which the paste was used the indications for terminating pregnancy were mainly pulmonary and cardiac lesions, in which avoidance of inhalation anæsthesia is an advantage. Table II shows that in 56 (nearly 80%) the method was successful without other operative procedures needing general anæsthesia. In most the abortion was complete, but in a few it was incomplete and needed ecbolics to complete it. In 15 cases (about 20%) the operation was unsuccessful. In those classed as complete failures the paste had no effect at all and abortion was effected under general anæsthesia by digital evacuation or by the introduction of bougies or a hydrostatic bag into the uterus. Partial failure means the production of an incomplete abortion with the paste and the use of other operative procedure needing general anæsthesia to complete it.

TABLE II—RESULTS OF THE PASTE METHOD OF TERMINATING PREGNANCY

Duration of pregnancy (weeks)	No. of cases	Average amount of paste used (ml.)	Average duration (hours) before onset of abortion	No. successful	No. unsuccessful		
					Complete failure	Partial failure	Total
12 or less	37	16·8 (8–23)*	27·7 (6–52)*	29	3	5	8
13–16	24	20·8 (15–40)*	43·5 (13–375)*	21	0	3	3
17–20	2	55 (30–80)*	..	0	2	0	2
More than 20	8	32·5 (15–70)*	19 (10–24)*	6	2	0	2

* Extremes

The figures, though not statistically significant, suggest that the method is more likely to be unsuccessful after the 16th week of pregnancy. Table II also shows that, on an average, the abortion can be expected to begin 24–48 hours after the injection of the paste.

At the suggestion of Mr. E. W. C. Buckell, late obstetric registrar at University College Hospital, the paste, mixed with an equal quantity of 'Neohydriol,' was inserted into the uterus of a patient (not included in the above series) who was 16 weeks pregnant and had pulmonary tuberculosis; 16 ml. of the mixture was injected, and complete abortion took place within 24 hours. Fig. 1 shows the paste, immediately after insertion, filling about the lowest quarter of the uterus. The fœtal spine can also be seen. Fig. 2 shows some of the paste still present in the uterus, and some in the left fallopian tube, after the abortion. Fig. 3 shows some of the paste in the pelvic portion of the peritoneal cavity four days after the abortion. Radiography thus indicates that the uterine contractions during the expulsion of the uterine contents may drive the paste along the fallopian tubes.

Our largest group, the schizophrenics, selected only by excluding hebephrenics, consists of catatonics, paranoids, and paraphrenics. The ability to lead a useful life outside hospital was restored in 30–40% of these cases. In this figure are included some patients who could be discharged but have no home to go to. In another 20–30% the most distressing symptoms have definitely improved. This is no small achievement in view of the years of misery, suffering, and struggling with delusional phantoms now spared the patient, and the general effect on the atmosphere of the hospital. Why the result of the operation is fully satisfactory in only a third of the cases cannot be answered from the small number of discharged patients. A parallel study devoted to those patients operated on in the same period and still in our hospital will provide a series for comparison.

(2) *Time of Operation*

Rebuilding of the personality on the new basis is always possible so long as one can be certain that emotional and intellectual life are preserved behind the screen of psychotic behaviour. Only expert observation will be able to judge this in long-standing cases of schizophrenic withdrawal and deterioration.

There is, on the other hand, no need for leucotomy in an early stage of the illness, except perhaps in quickly deteriorating "nuclear" schizophrenics not responding to insulin treatment. In all other cases not only should the usual less drastic therapies be tried first but also, in the event of their failure, the psychosis should be left to run its course as long as a spontaneous remission can be reasonably expected. Published figures, like those of Freeman and Watts (1946), give no proof that the results of workers who operate in early cases are much better than our own.

(3) *Operative Procedure*

If our theory is correct, the problem of the operation becomes one of quantities. The surgeon will be asked to produce enough frontal symptoms to combat the symptoms of the psychosis—enough euphoria against distress and depression; enough extraversion and distractibility against introspection and withdrawal; enough indifference and freedom from care and worry against obsessions, delusions, and fear. The dilemma obviously is between either producing too mild a frontal deficiency syndrome, with the consequence that the psychosis rules the patient's behaviour as before, or producing a too severe syndrome, with a resulting clinical picture as disturbing as the original illness.

It is less certain if these psychopathological quantities correspond to the amount of prefrontal lobe isolated by the operation. Perhaps isolation of certain parts of the area—e.g., the orbital region—is responsible for all (Hofstatter et al. 1945) or only some (Dax and Radley-Smith 1946) of the frontal symptoms. Perhaps the more or less complete severing of the thalamofrontal radiation represents the quantitative correlate to the clinical symptoms, a view strongly held by Freeman and Watts (1942), whose technique (incision in the plane of the coronal suture) was used in the present series of patients. From a personal communication of Dr. Freeman it seems that these workers now aim at the greatest possible completeness in the division of the white matter in this region. They also advocate a second operation 5–10 mm. behind the coronal suture in patients who do not recover from their psychosis after the first operation (Freeman and Watts 1946). All this, however, can be explained without reference to special bundles of fibres if we assume that the resulting mental change depends on the amount of prefrontal area isolated. Until the physiologist and pathologist can furnish more detailed information, this seems a reasonable working hypothesis.

(4) *Postoperative Treatment and Rehabilitation*

In the postoperative period the patient's life a personality are pliable and easy to mould, ready a systematic reconstruction. They are accessible psychological and occupational training, sometimes sedation and other physical treatments, all of whi were without avail before the operation. Re-educati of the injured brain is a new task for the psychiatr and for most psychiatric hospitals.

Without adequate facilities for reablement the operati should not be advised. Some details of the method u in this hospital were given by Berliner et al. (1945).

The result of our follow-up has strengthened the c for a prolonged convalescence in hospital before dischar should be considered. The patients, freed from th tribulations and worries, and their relations, impress by the patients' happiness and cheerfulness, urge t physician to discharge him. Three months should the minimum for re-education. Even then, only when home environment is favourable should the patient sent out on trial. Relations should be warned of difficulties they will have to face and instructed h to continue re-education; the family doctor should fully informed. There is no doubt that those who ha been patiently and tactfully supervised by their frier at home have adapted best. On the other hand, most our readmissions were due to lack of understandi and guidance in the home and to other adve environmental factors.

SUMMARY

The results are reported of a follow-up of 68 patie discharged from hospital after prefrontal leucoto out of a total of 170 patients operated on betwe February, 1943, and June, 1946. The patients h been at home for at least six months.

More than half these patients (a fifth of the tota who without the operation would have been hopel chronic invalids, earn their living, and more than thr quarters are usefully employed.

Working capacity and the patient's attitude to wo interests and hobbies, social, family, and sex life, described as well as personal appearance and prevaili mood.

From these findings a composite picture of the succe fully treated patient after leucotomy was abstract Its prominent features are well-known sympto observed after frontal-lobe damage due to trauma neoplasm. After leucotomy these features provide a n framework of personality in which the patient's men life has to be reconstructed.

In the light of this theory of the operation practic conclusions are drawn in regard to selection of cas time of operation, operative procedure, postoperati treatment, and rehabilitation.

We are indebted to Dr. P. K. McCowan for permission publish this material and for his advice, and to Mr. R. Beveridge, who operated on most of the patients. Our spec thanks are due to Miss M. A. Lane, senior psychiatric soc worker at the Maudsley Hospital, London, and to her studen who followed up some of our patients in the London area.

THE VIABILITY OF TREPONEMA PALLIDUM

C. E. LUMSDEN
M.B. Aberd.
LATELY MAJOR R.A.M.C.
From the Pasteur Institute, Shillong, Assam

FOR some months in 1943 field hospitals in Assam were without adequate facilities for dark-ground examination of material from penile sores. During this period, when capillary-tube samples from venereal sores were being sent to me by post or by courier, the question often arose of the reliability of this procedure, in view of the hazards to which such samples were exposed, some coming from isolated units in the jungle seventy or eighty miles away and taking four or five days in transit.

My colleagues could not give any categorical opinion about the normal expectation of viability of *Treponema pallidum* in such preparations, and the textbooks then available to us were not helpful. For instance, Topley and Wilson (1941) state of spirochætes that "some of the highly parasitic members, such as *T. pallidum*, are unable to survive outside the animal body for more than an hour or two." Stitt et al. (1938) merely state that exudate from chancres "should be examined fresh" with dark-field illumination. On the other hand, Muir and Ritchie (1937) state that, in sealed tubes, spirochætes may "retain their shape for days or weeks." Gradwohl (1938) is silent on this subject.

Accordingly I decided, in addition to the routine examination of specimens submitted from outside, to investigate the viability of *T. pallidum* in preparations made by ourselves from fresh untreated lesions.

METHOD AND FINDINGS

In 10 *consecutive* cases of typical Hunterian chancre of the penis in which I had just found *T. pallidum* on dark-ground examination, I made several preparations (the number depending on the quantity of serum obtained without undue discomfort to the patient), which were examined at intervals subsequently.

In cases 1–7, labouring as I was under the preconceived notion that *T. pallidum* was a delicate creature, several capillary tubes of serum from each case were taken, sealed, stored in the incubator at 37°C, and examined at intervals until the series of tubes was exhausted. In cases 1 and 2 typical motile *T. pallidum* was seen up to the seventh and sixth days respectively, and on the eighth and seventh days respectively morphological *T. pallidum* was readily identified but motility lost. This was encouraging, and, as it is difficult to obtain from a sore enough undiluted serum to fill more than six capillary tubes, I decided to examine the specimens on alternate days, as in cases 3–7.

In cases 1–7 (table I) *T. pallidum* remained viable and readily identifiable to the sixth day at least. In case 5 motile *T. pallidum* was seen in the last capillary tube, which was reserved until the tenth day before opening. In case 8 only two preparations were made as before, but these were kept at laboratory temperature and not examined until the tenth and thirteenth days, when both were found to contain numerous typical spirochætes still exhibiting natural movement. Case 10 was a similar preparation but had been inadequately sealed; on examination on the eleventh day it was found to be dried up, and no spirochætes were identified on emulsification of the residue in saline.

As the foregoing were consecutive cases, there seemed little doubt about the prolonged viability of the treponemata in the capillary tubes, and, to minimise labour, I decided to see how long the paraffined slide preparations remained positive—i.e., the original slide in which *T. pallidum* had been seen was reserved and examined daily. To avoid drying, I took care to use a fairly liberal drop of saline to mix with the serum and to ensure an adequate seal with the soft paraffin ring at the periphery of the coverslip. In each case several slides were made; some were kept in the incubator at 37°C, and some at room temperature. The findings are set out in table II. In every case *T. pallidum* continued to be readily identifiable and still motile from eight to fourteen days later. In case 14 morphological *T. pallidum* was seen on the sixteenth day on the slide kept at room temperature, but it was no longer motile. Usually the slides kept at room temperature gave better results, as they tended to dry less.

General Observations.—No special precautions were taken in making the preparations, the object being to collect the specimens of serum in much the same way as I would expect others to collect them for submission to the laboratory. The chief precaution was to ensure proper sealing of the capillary tubes and of the paraffined slide-and-coverslip preparations.

During the observations the daily room temperature varied between 5° and 18°C.

The presence of red blood-cells and of micro-organisms in otherwise reasonably good preparations did not appear to prejudice the result to any significant degree. There did not appear to be any great tendency for other bacteria to overgrow the spirochætes, and even in the incubated preparations, where there were large numbers of bacilli present, the spirochætes persisted quite well.

TABLE I—VIABILITY OF *T. pallidum* IN CAPILLARY-TUBE PREPARATIONS MADE FROM TEN CONSECUTIVE POSITIVE CASES OF TYPICAL HUNTERIAN CHANCRE

Case no.	Day of examination of preparation										
	1	2	3	4	5	6	7	8	10	11	13

+, typical morphological *T. pallidum* with characteristic motility.
R, kept at room temperature all the time.
?, morphological *T. pallidum* not showing motility.
—, no *T. pallidum* found.
*, this specimen had dried up.

In case 8, in which the tubes were stored at a room temperature of 5–18°C (41–64·4°F), *T. pallidum* remained viable ten and thirteen days. In case 10, in which the tube was not properly sealed, no spirochætes could be identified on examination on the tenth day.

In a further 8 cases the original slide preparations in which *T. pallidum* had been identified were sealed with soft paraffin and stored either at room temperature or in an incubator at 37°C. In each case *T. pallidum* was viable for eight to fourteen days. Viability was longer in the slides kept at room temperature.

In a subsequent experiment viability persisted thirty-four days.

These experiments confirm the findings of other workers, and attention is drawn especially to the reports of infection with syphilis from necropsy material.

I wish to thank Lieut. Arjan Singh Man, I.A.M.C., for his collaboration throughout the technical work.

INTRABRONCHIAL PENICILLIN FOR LUNG ABSCESS

EUGENE ROSENTHAL
M.D. Budapest
PROFESSOR EXTRAORDINARY, 1ST MEDICAL DEPARTMENT,
ST. ROCH'S MUNICIPAL HOSPITAL, BUDAPEST

In lung abscess conservative methods of treatment are successful only in exceptional cases, so that surgical treatment has been adopted as a routine. This practice was not changed by the advent of ultra short-wave therapy or of sulphonamides; but the introduction of antibiotics reopens the question.

In February, 1946, I first treated a case of pulmonary abscess with penicillin given systemically in a dosage of 240,000 units a day. This abscess, which was about 7 cm. in diameter and situated in the right lower lobe, decreased in size, while there was a fall in temperature, a reduction in the amount of sputum, and general improvement; but though the penicillin undoubtedly produced immediate benefit it did not lead to a final cure.

Endobronchial Application.—An attempt was therefore made to increase the concentration of penicillin inside the abscess cavity by introducing the drug through a plastic tube inserted into the appropriate main bronchus after anæsthetising the pharynx and air-passages. Penicillin 50,000 units was given in this way into the main bronchus on the affected side, the patient being placed in a suitable position to enable the penicillin to reach the abscess cavity with the aid of gravity. The procedure was the same as that used in bronchography. The patient was instructed to keep in this position for three or four hours or longer if possible. An essential point was the control of coughing.

After this treatment there was an immediate fall in temperature and less sputum; the abscess cavity then got steadily smaller and ultimately disappeared completely. The penicillin was given intrabronchially at intervals of two or three days; 3–8 treatments being given in all.

Inhalation.—On the days when penicillin was not applied intrabronchially it was given by inhalation from an atomiser. This apparatus (fig. 1) was connected to an oxygen cylinder and the expired carbon dioxide was rebreathed, inducing deep respiration, which appears to be essential for obtaining good results from inhaling penicillin. The daily dose was 50,000–80,000 units, divided into two or three inhalations. Since penicillin, though thermostabile in a powder, needs to be kept cool when in solution, the glass container was enclosed in a second container holding ice-water (fig. 2). To prevent cross-infection by the inhalation set when used by one patient after another, each part of the apparatus is sterilised.

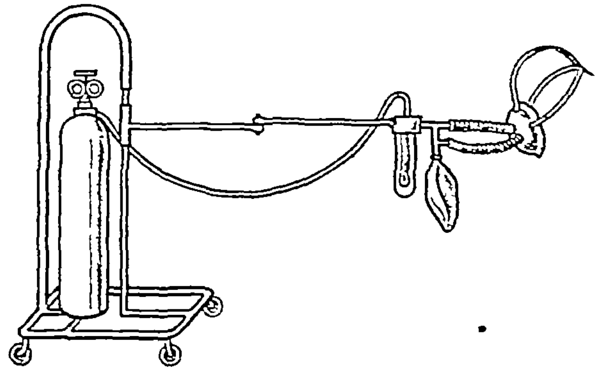

Fig. 1—Penicillin atomiser and inhaler.

The regular inhalations are a useful supplement to the intermittent intrabronchial therapy, but it would probably not cure a lung abscess if used alone, because the penicillin is dispersed through all the air-ducts and thus does not maintain a sufficient concentration in the abscess cavity.

Results.—Of 11 cases treated with intrabronchial penicillin only 1 was lost: an abscess in the right upper lobe in a patient aged 69 in a bad general condition caused sudden death. The 10 other cases were definitely cured.

In 1 case there were two relapses, four and five months after the end of the first febrile period. Both of them were controlled by further treatment with systemic and intrabronchial penicillin.

In 1 case tyrothricin was given intrabronchially, with a good result; the reduction in the amount of sputum seemed to take place earlier and faster than was usual with penicillin.

SUMMARY

Intramuscular penicillin may be expected to produce improvement but not final cure in lung abscess. The method of choice appears to be the intrabronchial administration of penicillin supplemented by frequent inhalations.

−, no *T. pallidum* found.

Desiccation of the preparation in the incubator was the factor mainly responsible for impairing the longevity of the spirochætes. On the whole, the preparations kept at room temperature were more satisfactory.

In both tube and slide preparations the numbers of spirochætes appeared to be gradually reduced. Movements became more and more sluggish and finally ceased. In no case was there any evidence, so far as could be detected, of any multiplication of the spirochætes, even at incubator temperature.

On one occasion a spirochæte of *gracilis* type was also identified besides *T. pallidum* and remained viable somewhat longer.

Subsequent Experiences.—Unfortunately I could not pursue the investigation systematically beyond this point, but from time to time I made random observations and had positive slide preparations in which motile *T. pallidum* persisted for even longer periods, the longest being 34 days.

DISCUSSION

That *T. pallidum* is fairly viable outside the human body is not generally appreciated, nor is it generally recorded in the standard textbooks; but the observations here recorded are not unique, as I have since ascertained. A few references are given by the Medical Research Council (1931) to reports dating as far back as 1906, when Beer first reported that in a slide-and-coverslip preparation he had seen *S. pallida* still motile after 33 and 50 days.

In human necropsy material kept in the refrigerator the spirochætes have been found motile after 48 hours, and syphilitic necropsy material can remain infective for at least 24 hours. Enormous numbers of *T. pallidum* may be present in, for instance, macerated fœtuses, suggesting that *T. pallidum* can multiply in dead tissue under anaerobic conditions. Truffi found motile *S. pallida* in a primary chancre 52 hours after death of the patient. Gastou found the organisms in syphilitic child's liver up to 10 days after death, and Neisser found it in a stillborn fœtus 50 hours after birth (Neisser 1911).

Accidental infections, though rare, can and do undoubtedly take place in the necropsy room and in the laboratory. Hoffmann (1927, 1929), reviewing 40 reported cases (including some of his own), concluded that at least 22 of these were certainly genuine cases of this type. Of these 22 cases of accidental infection, 17 were contracted from necropsies on congenital syphilitic children or fœtuses; 3 from freshly acquired cases o syphilis; and 1 from the dissection in the laborator of the brain from a case of general paralysis. Th primary lesion in the accidentally infected person wa on the fingers in 19 cases, on the neck in 1 case, and i the other 2 cases the site of the accidental lesion wa unspecified—presumably the hand or the fingers. I 14 cases the persons so infected were the doctor performing the necropsy, in 6 cases necropsy-roon attendants, and in 2 cases laboratory assistant handling specimens outside the necropsy room afte the necropsy (the brain of the general paralytic bein one of these specimens).

It is commonly assumed that the risk of accidenta transmission of syphilis by therapeutic transfusion o blood is negligible, and before 1939 there was no repor of any such case in Britain. However, some 70 well authenticated cases have been recorded in America an on the Continent since the first description by Fordyc in 1915 (McCluskie 1939). In almost all of these th infections took place when the donors were in th primary or secondary stage of syphilis. McCluski (1939) reported a case in which syphilis was transmitte by a donor still in the pre-chancre stage and whil the Wassermann reaction was still negative; and h summarised 2 similar classical cases of this categor reported by Post and Cooney (1933) and Pautrie (1936).

Whether the practice of refrigeration of stored bloo in blood-banks would itself necessarily ensure rapi death of any spirochætes present may also be questione in view of the reported resistance to cold of the organisn in culture. Kissmeyer (1923), working with pur cultures obtained from the State Serum Institute i Copenhagen, reported having subcultured *S. pallida* after keeping it at −16°C for 3 months but stated that at 2°C they died after some days. Krantz (1923 showed that cultures of *S. pallida* could multiply a room temperature; after culture at 0–5°C for days the spirochætes were readily recognisable, though non-motile, but viability persisted, since they grew on subculture. Krantz also froze his culture at −20°C for an hour and found the organism still strongly motile 48 hours after thawing. More recently it has been shown that when spirochætes are maintained in the frozen state at −78°C they may remain virulent for at least 3 years (Turner and Fleming 1939), but at −20°C virulence disappears within 2 months (Turner 1938).

While I was actively interested in this question of the viability of spirochætes, Selbie (1943), at the Bland-Sutton Institute of Pathology, Middlesex Hospital, was investigating how long *T. pallidum* remained infective in stored blood, plasma, and serum at low temperatures. Suspensions of rabbit chancre in rabbit plasma were stored at 5°C and tested for virulence at various periods thereafter. He found the period of survival to be about 6 days—rather longer than the period found by other workers investigating the same problem. Despite this, he considered the transmission of syphilis by stored blood to be unlikely, because "in the first place, the numbers of spirochætes in the infected plasma were many times greater than those encountered in human syphilitic blood; secondly, the infected plasma was injected, not into the blood-stream, but into a sensitive tissue, thus largely precluding the operation of the natural defences of the host."

SUMMARY

In 10 consecutive cases of penile chancre in which *T. pallidum* had just been found, series of capillary tubes of serum were prepared, sealed, and stored for subsequent examination.

In cases 1–7 and 9, in which the tubes were stored in an incubator at 37°C (98·6°F), *T. pallidum* remained viable at least six days (in case 5 ten days

Of 11 cases treated by this method 10 completely recovered.

I wish to thank Dr. L. Laub, late chief of the department of laryngology, St. Roch's Hospital, for his skilled coöperation in applying the local treatment.

ADDENDUM

Mr. C. Price Thomas, of the Brompton Hospital, was good enough to draw my attention to the fact that, about the same time, similar experiments were carried out, with similarly good results, by Mattei et al.[1] at Marseilles.

AN EASY TECHNIQUE FOR INTRAVENOUS CANNULISATION

Allan Clain
M.B. Cape Town
HOUSE-SURGEON, ROYAL NORTHERN HOSPITAL, LONDON

The technique described here has been used on twenty-five patients at the Royal Northern Hospital, Holloway. It is a simple, speedy, and effective method for introducing a blunt cannula into a vein.

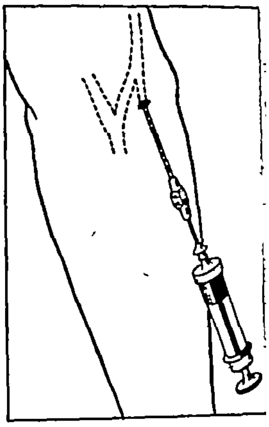
It has advantages over the West Middlesex needle method in that it is much easier and does not need a vein junction for its performance. Experience shows that the West Middlesex needle tends to pierce veins or slip past them unless one enters a fork where two veins join—e.g., at the origin of the cephalic vein at the back of the wrist. The method described here can be used at this point, the bend of the elbow, the long saphenous vein in front of or above the medial malleolus, or any vein which can be distended sufficiently for an intravenous needle to enter. It does not destroy the vein used and is successful in all but extremely collapsed or very small veins and thus has definite advantages over a tied-in cannula. It is also much quicker to perform and the whole transfusion can be set up in five minutes.

Requirements.—These are simple and will be found in most wards:

(1) a medium-sized (about S.W.G. 18) straight blunt cannula of the West Middlesex or Jubé type; or alternatively a sharp-ended intravenous transfusion needle which has had its tip filed off;
(2) a fine lumbar-puncture needle which will go through the cannula easily and protrude from its tip for $^3/_4$–1 in.;
(3) a small syringe;
(4) a fine hypodermic needle;
(5) a small scalpel;
(6) an adapter.

Procedure.—Choose any suitable vein and inject local anæsthetic intradermally about $^1/_2$ in. distal to the point where it is proposed to enter the vein. All that is necessary is to raise a small weal. While the local anæsthetic is taking effect, set up the intravenous apparatus in the usual way and attach the adapter, which is going to fit into the cannula, to the end of the rubber tubing. Next make a short skin incision (less than $^1/_4$ in. is sufficient) and push the cannula through this to ensure its going through easily when the time comes. The lumbar-puncture needle is attached to the syringe which has been used for the local anæsthesia, and the cannula is slid over the needle so that its base lies next to the base of the lumbar-puncture needle.

The vein to be used is then distended. If the long saphenous vein is being used, it is useful to have a sphygmomanometer cuff round the calf. Next, insert the lumbar-puncture needle and the tip of the cannula through the skin incision (see figure). This latter point is important, since it prevents difficulty at a later stage If the cannula tip is left outside the incision it tend to become caught on the edge of the skin in passin through the incision at an acute angle. Enter the vei in the usual way about $^1/_2$ in. proximal to the incision and slide the needle into the vein slightly further after ensuring, by withdrawing blood, that the vein has been entered. Then slide the cannula along the needle into the vein with the right hand, steadying the syringe with the left as this is done. There will be a definite feeling of resistance as the cannula enters the vein; it is then slid right in up to its base, and the syringe and needle are withdrawn after compression has been released. Blood will then trickle out of the cannula, and th adapter is attached and the transfusion started. Th cannula and tubing are strapped to the part in th usual way, but it is unnecessary to splint the limb unles the patient is restless or a vein at the bend of the elbo is being used. When the time comes, the cannula i simply pulled out and a small dressing applied.



My thanks are due to Mr. Hamilton Bailey, F.R.C.S., fo advice and encouragement, and the nurses of the Roy Northern Hospital for patient assistance.

GLANDULAR ENLARGEMENT IN ADULT

REVIEW OF NINE CASES

H. M. Royds Jones
M.D. Lond.
SURGEON, ORIENT STEAM NAVIGATION CO

During the late war I saw occasional cases of enlarg lymphatic glands, with or without a rash and pyrexi where the blood changes did not correspond to those glandular fever.

These cases presented some difficulty in diagnosis, an there was always doubt whether they were isolat atypical cases or a separate syndrome. For this reas this small group of cases, occurring on board ship, reported, and because the pathological investigatio did not seem to confirm the clinical diagnosis.

The cases were distributed over two voyages in t same ship: 7 on the first voyage and 2 on the secon

The group of 7 patients were seen within a peri of 16 days, 5 of them being members of the crew a 2 passengers. All 5 of the crew were about 21 yea old. The histories of all the cases were similar, exce where stated.

The patients first complained of a "lump behind t ear," which proved to be a painful enlarged lymph-glan Further search showed that glands were enlarged both sides of the neck, in the axillæ, and to a less extent in the groins. The spleen was impalpa throughout the illness, and the patients were apyrexi In 5 cases there was a macular rash on the chest (unnotic by the patients), which faded in a few hours. A six patient had a macular rash on the face only, and t remaining patient had no rash at all. Blood films do on board showed a moderate leucocytosis (11,00 14,000 per c.mm.) and an increase in mononucle (14–25%). These cases were diagnosed as glandular fe (infective mononucleosis).

Cases 1, 2, and 3, in which the disease began March 19, 21, and 24, 1947, respectively, were furt

Medical Societies

ROYAL SOCIETY OF MEDICINE

Child Guidance in the Health Service

At a meeting of the section of pædiatrics on Nov. 28, with Dr. W. G. WYLLIE, *the president, in the chair,* a discussion on the place of child guidance in the new health service was opened by Dr. IAN SKOTTOWE. The child-guidance movement in organised form dates, he said, from 1929; and it embraces all child psychiatry except gross mental deficiency. The movement has become highly specialised; and it is perhaps a little isolated from general medicine and other branches of psychiatry. Account must be taken of more specialties than are implied by dynamic psychopathology alone; and there are strong arguments for integrating child guidance with the new health service. Of 100 children up to the age of 16 seen at the psychiatric clinic of the Royal Buckinghamshire Hospital, Aylesbury, 64 were referred by family doctors: 31 were aged 14–16: and no fewer than 33 had significant somatic disease requiring treatment in another special department, while in a further 9 some somatic investigation was required. Of the 100, 43 needed skilled psychotherapy, 19 the services of an educational psychologist, 18 social service, and 10 residential treatment of one sort or another. From recent surveys had emerged the idea of (1) child-guidance centres, associated with schools and not controlled by doctors, and (2) child psychiatric clinics at general hospitals to which children needing treatment would be referred. This concept had been criticised because of the so-called "dual administration"; but there was nothing inherently impossible about such an arrangement.

Dr. A. A. E. NEWTH emphasised that most maladjusted children are basically normal; but close medical supervision was important. The unification of psychiatric services, sometimes advocated, had its drawbacks; was the mental-hospital psychiatrist likely to be sympathetic to the mild psychological mishaps of childhood? Moreover, too close an association of child-guidance clinics with other mental services might enhance the diffidence of parents in seeking advice. In Dr. Newth's experience most cases were referred initially by teachers, only some 8% being sent in the first place by doctors. Very distressing behaviour might result from trivial maladjustment, while severe maladjustment might evince itself by only slight behaviour disorder. Educational psychologists should not be shouldered with the responsibility of classifying the disorders, for these cases, he said, were complicated and had many and deep roots: the identification of these roots was the more difficult because the very person reporting the disturbance was sometimes largely responsible for it. Thus the American idea of a team was inescapable. The trouble was often sown in early childhood, symptoms becoming apparent only by contrast with others at school: it was therefore reasonable for educational authorities to have a hand in dealing with the disorder. Buildings for the centre should, Dr. Newth suggested, be near to, but separate from, the school: and mentally deficient or psychotic children should not be seen there. Schemes for such centres could not be complete in themselves; for the backing of children's hospitals and of pædiatricians was essential.

Dr. MILDRED CREAK agreed that symptoms are no guide to the condition; so initial investigation should be by the experienced and expert. The waiting-list was a major problem at most clinics: and a first step must be to remove it. The psychiatric problems seen in children's hospitals differed from those at clinics, for they included a large proportion of psychosomatic disturbances. Parents naturally sought a physical explanation for psychogenic disturbances; and it was most important that such states as hysterical vomiting should be quickly referred to the psychiatrist before they became fixed. Clinics whose work was confined to diagnosis tended to widen the gap between general medicine and psychiatry; and students should have the chance to see cases being treated. The psychiatrist working alone was as helpless as the surgeon alone; the psychiatrist should be supported by an educational psychologist and a psychiatric social worker.

Dr. H. S. BRYAN held that, since psychosomatic disorders were so common in children, it was more important for the children's psychiatrist to have had experience in pædiatric departments than in mental hospitals. If child guidance was to be fully effective it must become preventive by reaching every child at an early age. The health visitor might, by extra training, become the spearhead of the attack.

Prof. C. W. VINING was opposed to division between pædiatrics and child psychiatry.

Dr. LETITIA FAIRFIELD contended that child-guidance clinics should be multiple rather than uniform in character. There was need for the screening of cases, and teachers and other school authorities should be able to deal with "naughty children." Up to 1929 pædiatricians had contributed nothing to child guidance "except to give thyroid to mongols"; but of course that was now changed. In a non-equalitarian country such as Britain doctors and nurses in hospitals did not understand the situation in schools from which cases were referred.

Dr. L. G. HOUSDEN said that parents should be enabled to guide their children. The attitude of modern young people was epitomised in an essay by a nineteen-year-old girl who wrote: "I shall send my child to church and Sunday school. Then if it does anything wrong, they can't say it was my fault."

Dr. J. D. KERSHAW deplored the defeatism by which the psychiatrist lurked in the hospital and advanced half-way to meet the maladjusted child, at the child-guidance clinic. He should be based on the clinic and from there move forward the whole way to meet the child. Dr. Kershaw suggested that maladjusted children would be fewer if parents were provided with the physical means for affording the right environment. The child should be considered in relation to his home background and his future.

Dr. A. F. ALFORD (Ministry of Education) said that the child-guidance clinic was to be the pivotal point between the educational service and the National Health Service: in treatment there would be no watertight division between the personnel of the two services, and the patient was to be treated as a unity.

MANCHESTER MEDICAL SOCIETY

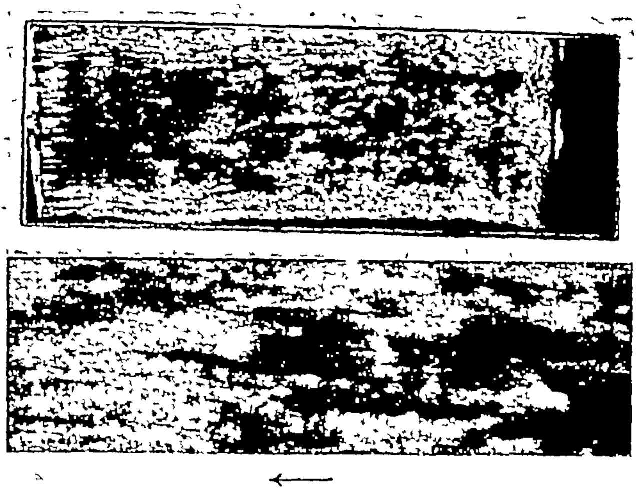
Prognosis of Mental Disorders

AT a meeting of this society on Nov. 5, Dr. G. HOWARD KITCHING, opening a discussion on the prognosis of mental disorders, said that the patient and his relatives want to know not only whether he will get better, but also whether he will be completely well, and what effect the illness will have on his future, on his work, and on his married life. All mental disorder arises from one, or from combinations of two or more, of four groups of precipitating causes: weaknesses or tendencies in the innate constitution; the tendency for mental illness to occur at the epochal crises of life (puberty and the menopause); exceptional mental experiences such as "shocks," which to operate must be major experiences affecting the patient's self-esteem; toxic or structural damage to the nervous or other systems.

He grouped mental disorders under four principal headings:

A Those in which cerebral capacity is reduced. If the condition is congenital the case is one of mental defect of varying degree, if acquired, the case is one of organic dementia. Confusional states may be included in this group. The prognosis of mental defect is, of course, radically stationary and hopeless. In the inorganic dementias the ultimate tendency is downhill, but often with surprisingly long remissions, especially if the onset is acute and associated with some toxic cause.

B Those in which mental coördination is reduced. This group includes all those diverse conditions which have as a fundamental feature a discrepancy between thinking and feeling: the schizophrenic paranoid series of illnesses. In general the prognosis of this group of disorders is bad. Cases with an acute onset have a better outlook than those of



Above: streaky blood film on microscope slide.
Below: enlarged view of part of film, showing typical knobs at head of each streak.
Arrow indicates direction in which film was spread.

had confused the streaky films with the phenomenon described by Fahraeus,[1] in which a large drop of blood is allowed to flow over a slide, and a granularity gradually appears within it. This granularity is in fact rouleaux formation and its degree naturally runs parallel to the E.S.R.

That streakiness did not represent rouleaux formation was shown by microscopical examination, for though the cells in the rivulets were closer together than elsewhere on the slide they were not usually even in contact with one another. Nevertheless its very close parallelism with the E.S.R. suggested that streakiness had some connexion with rouleaux formation; and we felt that it might represent a preliminary stage in the process—a coming together of the cells before they formed chains.

Between 1939 and 1946 large numbers of cases were collected which confirmed the close correlation between streakiness and the corrected E.S.R.; but further investigation was impracticable during this period. Early in 1946 we saw a case of myelomatosis with an extremely rapid E.S.R. but no streakiness—the first gross exception to our rule that we had come across. Moreover the blood films of this patient, though perfectly homogeneous to the naked eye, showed extreme rouleaux formation under the microscope. Clearly, then, rouleaux and streakiness were fundamentally independent of one another. Another significant finding in this case was an extremely high serum-globulin and a normal plasma-fibrinogen. About this time we obtained some human fibrinogen and showed that, as the plasma-fibrinogen was increased, the E.S.R. and streakiness increased quantitatively. These two sets of data forced us to conclude that, whereas rouleaux formation and E.S.R. increased with increasing amounts of either fibrinogen or globulin, streakiness was produced only by an increased amount of fibrinogen.

In view of this finding it seemed possible that streakiness might be due to the precipitation of fibrin—that in drawing out a blood film one partially defibrinated the blood. This possibility was excluded by showing that streakiness was equally well developed in oxalated or citrated blood. This observation was important, since it enabled us in future experiments to work with blood containing an anticoagulant.

We next found that minute traces of bile-salts added to the plasma not only brought sedimentation to a standstill but also completely ironed out streakiness. Both phenomena were eradicated by a lowering of the surface tension, so presumably both phenomena depended on surface forces. It is known that rouleaux formation is the result of surface forces acting at the interface between the cells and the plasma; was it possible that streakiness was produced by surface forces acting at the interface between plasma and air, or between plasma and the glass surface of the slide? If that was the case one would expect that plasma freed from cells would show streakiness; but all our attempts to demonstrate this were in vain.

FIBRINOGEN

We finally consulted Prof. E. K. Rideal, of the Royal Institution, who on examining our streaky films said that the appearance was undoubtedly due to the molecular aggregation and partial denaturation of the protein in the plasma. He suggested that we should again try to demonstrate streakiness in plasma films. This we did, and, after many failures, one of us (T. H. N.) suddenly noticed that if, while the plasma film was still wet, one examined its surface by reflected light, one could detect a series of longitudinal ridges. Once noted the effect was obvious; and we soon demonstrated that the degree of waviness of plasma films ran parallel to the streakiness of the corresponding whole-blood films. Moreover, when we made films from the serum of blood which gave streaky blood films and wavy plasma films, the serum films were always perfectly smooth. Thus we obtained striking confirmation of Professor Rideal's suggestion that streakiness was due to a molecular aggregation of the protein, and of our own earlier conclusion that streakiness depended on the fibrinogen and not on the other plasma-proteins.

Mr. E. M. Shooter, one of Professor Rideal's research-workers, has since pointed out to us why this should be so: for molecular aggregation is much more likely to occur with the elongated molecules of fibrinogen than with the much less elongated molecules of globulin and albumin. Since then we have found two further cases with a very high E.S.R. and little or no streakiness, and in both cases the globulin has been much raised and the fibrinogen about normal. Further, Mr. Shooter gave us a small quantity of human γ-globulin with which we increased the E.S.R. to a high figure without producing any streakiness.

CONCLUSIONS

Further work has confirmed that streakiness gives a useful clinical indication of the plasma-fibrinogen level; that in the great majority of cases it is a useful indication of the corrected E.S.R.; and that a combination of the observation of streakiness with a measurement of E.S.R. is a convenient method for detecting those rare cases in which there is a gross increase of globulin with little or no increase in fibrinogen.

. . . It should not be denied that the long-run aim of societies aspiring toward human freedom is to get rid of power, and to bring into existence a free man's commonwealth in which coercion is neither threatened, applied nor desired. This is the thread of anarchist idealism that appears in all uncompromising applications of the key conception of human dignity. When Engels wrote of the eventual "withering away of the state" he was voicing the hope, though not necessarily the certainty, of the radical democrat. In our day, however, the probability that we can reduce power to the vanishing point seems very remote indeed. The urgent task is to chasten and subordinate power to the service of respect.—Prof. H. D. Lasswell at New York Academy of Medicine, Nov. 14.

penicillin nonad tulle

The efficacy of the local application of penicillin has been established by its use in the forms of powders, solutions, creams, and ointments. A new development is the introduction of Penicillin Nonad Tulle. This non-adherent sterilized gauze dressing of wide mesh is impregnated with an emulsifying base of soft paraffin and anhydrous lanoline, containing 1,000 units of penicillin per gram.

Submitted for trial in hospital practice, including special branches of surgery, Penicillin Nonad Tulle has been welcomed as a dressing for infected wounds and burns and for operation wounds, including those of eyes, ears, and nose, and those of skin-grafting.

insidious onset, and the prognosis is much affected by the duration of the condition. Obsessional disorder may also be included under this heading.

C. Those in which control is reduced. In these, affective disorders, or disturbances of feeling, show themselves as excess of elation, depression, or anxiety. The response of affective disorder in general to electro-convulsive therapy (E.C.T.) is specific and dramatic, and it successfully cures many of the minor cases as well as most of the major ones.

D. Reactions to situations in which the provoking situation appears to be a predominant factor. This group includes most of the psychoneuroses, and hysteria and anxiety hysteria. A strong element of constitutional predisposition has to be postulated in the patient, for the situations which provoke these disorders are fundamentally common to all people, whereas the neurotic reactions are not.

He considered prognosis collectively and individually. The number of people certified annually in any community is an index of its mental-hygiene movement. A good supply of psychiatric social workers and a vigorous mental-hygiene movement increase the number of certified cases, because they help in the disposal of cases to appropriate hospitals. In England the number of people under certificate is 5 per 1000 population. In any community the amount of serious crime varies inversely as the number of people certified, and one may take it that one mental-hospital bed is roughly the equivalent of one prison bed. Discharge-rates, he considers, are completely fallacious and mean nothing. The average length of stay in an institution is more than 10 years, or one-sixth of the duration of life. Statistics tend to show that psychosis is essentially a chronic and relapsing illness, analogous in medicine to gout, allergy, psoriasis, and diabetes. Statistically, the value of new therapeutic procedures—such as insulin shock for schizophrenia—is extremely problematical.

Of individual prognoses, that in cases of affective disorder has been completely altered by E.C.T. The natural prognosis of involutional depressions was that a third got well, a third remained stationary, and a third went downhill. With E.C.T. a recovery-rate of 80% or over may be confidently expected; and this treatment is almost equally valuable in states of elation, which are much less common than depressive states. It appears to have little real value, however, in schizophrenia or other psychoses.

The prognosis of schizophrenia remains baffling, for the diagnostic criteria vary from country to country, and even from worker to worker. Most workers favour treatment by insulin shock therapy, which reduces the duration of stay in hospital and produces a higher percentage of remissions in acute cases; but such improvements are often not maintained, and the long-term results tend to approximate to those of the untreated disorder.

Prefrontal leucotomy has also altered the prognosis of mental disorder. The results are difficult to assess, because—since it produces irreversible changes—it is not tried (except by uncritical enthusiasts) in early cases until other methods have failed. It cures many depressive and agitated states which have failed to respond to E.C.T., has produced good results in schizophrenia, and in many cases has changed a socially unacceptable psychosis into a socially acceptable one. Drug-addictions, including alcoholism, have a bad prognosis, and need psychotherapy combined with institutional treatment. One authority has estimated that 10% of cases are cured and remain well for three years. Statistical studies of the psychoneuroses and of the value of psychotherapy are at present almost valueless because they depend too much on subjective assessments made by patient and doctor.

Reviews of Books

Diseases of the Chest with Emphasis on X-ray Diagnosis

E. H. RUBIN, M.D., attending physician, division of pulmonary diseases, Montefiore Hospital, New York. London: W. B. Saunders. 1947. Pp. 685. 60*s*.

Dr. Rubin, in his preface to this elaborate volume, says that he designed it for general practitioners, sanatorium physicians, medical students, and radiologists. It is doubtful whether any specialised textbook has ever been written which could appeal to so varied an audience, and this one is no exception. It is far and away too detailed for the busy general practitioner, and most of it demands a knowledge of radiology and clinical pathology which no medical student could possess. Considered as a book by a specialist for specialists it has much to recommend it, and in some ways it breaks new ground, differing from other books on chest diseases in its emphasis on surgery and radiography. In the sections on suppuration, tuberculosis, and neoplasms, the author always gives a reasoned evaluation of surgical treatment based on his own wide experience, and in addition his brother, a thoracic surgeon, has contributed a brief and well-written résumé on surgical procedures in the chest. Dr. Rubin undoubtedly has a profound knowledge of chest radiology, and his analytical approach to interpretation should be followed by all chest physicians. Many of his descriptive terms for X-ray pathology are unhappy, however, and there is insufficient attention to the radiological points which help in differential diagnosis. As against these faults of omission, the book is a mine of detailed information readily found through an excellent index. It is ideal reading for higher medical examinations.

Psychology of Women

Vol. II. *Motherhood*. HELENE DEUTSCH, M.D., associate psychiatrist, Massachusetts General Hospital. London: Research Books. 1947. Pp. 439. 25*s*.

THESE volumes, the first of which we reviewed last year (1946, ii, 946), are frankly a psycho-analytic interpretation, and may seem at first reading to exalt the psychic at the expense of the somatic manifestations of disordered function. It is startling, for example, to be told that a woman is capable of postponing the delivery of her child for psychological reasons; yet the converse—that miscarriage can be induced by anxiety and other psychic states—is a commonplace, and there is no intrinsic difference in the two. That unconscious resistances to the idea of pregnancy can hinder conception is now suggested by physiological evidence, and the cases quoted by Dr. Deutsch strongly support such findings from the psychological angle. She is at her best when discussing purely psychological situations—the relations of stepmothers and stepchildren, of man and wife, of foster-mother and adopted child, and the adjustments which all women must make at the climacteric. With her evidently wide experience, and her insight into conscious and unconscious mental processes, she sheds many a sharp beam of light on human antics, and sets the reader thinking on rewarding lines. She brings home with uncommon force the great variety of things people do, and more especially the things they do, willy-nilly, to their children. Again and again the grown person tries to act out with her mate or her children some situation from her own childhood which left her dissatisfied; and of course the same is true of men. Carrying so much bias for disaster as we do, the wonder is not that few achieve the ripeness which is all, but that any do; and perhaps even these have more often to thank the benign patterns of a healthy soma than the wisdom and virtue of a mature psyche. Dr. Deutsch is good at pointing out those aspects of the psyche which most commonly fail to ripen.

Urologic Roentgenology (2nd ed. London: H. Kimpton. 1946. Pp. 259. 27*s*. 6*d*.).—This compact little book by Dr. M. B. Wesson, ex-president of the American Urological Association, was originally written for radiologists and physicians interested in urology. There have been great technical advances since the first edition, and the extensive use of intravenous pyelography now demands some knowledge of interpretation from all members of a hospital staff. All the abnormalities and diseases of the genito-urinary tract are adequately described, but special emphasis is laid on the commoner ones. The illustrations are liberal and excellent, and the text is so well written that it is a pleasure to read.

THE LANCET

LONDON: SATURDAY, DEC. 6, 1947

Advisers of the Boards

SURPRISE will have been felt in many quarters at ast week's advertisements in our columns for whole-time psychiatrists to certain of the regional boards. What is to be their function, and are these appointments to be followed by similar ones for other specialties? If so, where is the process to end?

The general expectation had been that whole-time professional appointments to the regional headquarters staff would be limited to the chief administrative officer—with perhaps one or two subordinates acting as his assistants—and that he would be concerned with administrative rather than professional matters. The simultaneous appearance of advertisements from several regions suggests that the move in a new direction originated from headquarters in the Ministry rather than by local initiative. If psychiatrists are needed to help with the immediate office work at regional headquarters, it might have been supposed that they would be part-time advisers already holding key positions in the psychiatric service in the region. The present proposition is quite different; for the new posts are permanent and whole-time, and carry salaries second only to those of the chief administrative officers themselves. In the absence, therefore, of any official statement explaining the purpose of these appointments it seems fair to assume that an important principle is at stake. The tendency they imply might easily lead to a form of "officialism" very far removed from the hopes of many who have warmly supported the regional idea. A primary object of the proposed organisation, as we understood it, was to give the regional boards the benefit of advice and guidance from the best medical opinion in the region; and though it is true that no specific provision is made by the Act for medical advisory committees to the boards, the consequences of a failure to establish such machinery would be serious. We cannot now afford to dispense with an arrangement which has been handed down to us in the best traditions of the voluntary hospitals. And if there is anything about which the medical committee of a hospital has a right to be sensitive, it is the making of whole-time appointments to key positions without any reference to it.

We are here in deep water, and it is surely time to look again at first principles. Many of the questions that the boards will have to consider will be closely analogous to those that confront the individual voluntary hospital. The relative priorities of this or that branch of medicine and their claims on the available resources will need to be debated Sooner or later the whole of the medical staffing in the region will have to be revised, and all kinds of new appointments made. How are these matters to be discussed and settled? Either the board can settle these things itself, relying on the advice of its chief administrative officer and of those of its own members who happen to be medical men; or it can appoint properly constituted medical advisory committees representative of all the various interests in the region, and take the advice of their accredited representatives before reaching its own decisions. Surely these alternatives have only to be clearly stated for it to be obvious that the latter method is the right one. If then the need for medical advisory committees is clear, is it wise at this early hour to appoint whole-time specialists on the lines indicated in the recent advertisements, before the medical advisory machinery has had a chance to function? For what whole-time specialist, once attached to the staff of the board as its privileged adviser, is going to look with favour on the establishment of an advisory committee by which his advice will be criticised? If this path is followed it is only too probable that all hope of the evolution of satisfactory medical committees for the region will die away.

Progress in Cancer Research

A PICTURE in *Nature*[1] of some little white balls, 200 A in diameter, lighted on one side and casting a shadow on the other, together with the caption that they were derived from lactating tissue of high-cancer-strain mice, provoked from the uninitiated the query "Are these really the cause of cancer?" This question was discussed at a meeting of the Royal Microscopical Society on Nov. 19 and it seems that we still do not know the answer—unless perchance it can be supplied by the editor of *Life*, in whose pages appear the only available picture and account of similar particles obtained in similar studies in the United States[2]

Previous biological tests showed that milk, tumours, blood, and some normal tissues derived from high-cancer strains of mice contain an agent which under certain specific conditions can produce mammary tumours. When water extracts of such material were spun at high speed they yielded a deposit, including this agent, which was thought to consist of very small particles. Professor PASSEY and his associates at Leeds set out to determine whether these particles could be rendered visible by electron microscopy and whether any of the particles which appear in photographs represent the active extractable agent. By a suitable technique clear-cut pictures of rounded particles 200 A in diameter were eventually obtained from, and only from, milk and tissues of high-cancer lines. At the Royal Microscopical Society's meeting the investigators met criticisms in respect of the size and shape of the particles and the treatment of the extracts, but they did not claim finality or even satisfaction. They are handicapped by having only the occasional use of an elderly temperamental instrument from which too much is being asked, and extraneous difficulties are always hard on biological studies, which impose their own exacting conditions. Hence progress has inevitably been slow. Nevertheless if these particles are the agent, in single units or conglomerations, it is a big advance to show that they can be displayed by electron photography.

‘MYANESIN’

The new
muscle relaxant

‘Myanesin’ has now been administered in some five thousand cases. Its value as an abdominal relaxant during surgery has been abundantly confirmed. ‘Myanesin’ was discovered in the B.D.H. Research Department. It is an entirely synthetic substance of known and constant chemical composition [α:β-dihydroxy-γ-(2-methylphenoxy)-propane]. ‘Myanesin’ is now available as a 10 per cent. solution in ampoules of 10 ml., issued in boxes of 3 and 12 ampoules.

for children's hospitals to establish them. It would be a mistake, however, to shape our plans for the future in accordance with present experience of the sources and types of children treated; for in an area which is exceptionally well served only two-sevenths of the modest requirements laid down by BLACKER[1] and others are met. Until a service is nearly adequate, sampling by clinic records is quite arbitrary, because the case-load of a clinic is quantitatively and qualitatively merely a reflection of the reputation, interests, and capabilities of the clinic's staff. Another principle to be observed in planning is that first consideration must be given to the interests of the children and their parents rather than to any popular administrative doctrine such as the contemporary urge for unification

The solution proposed by BLACKER and supported in a Nuffield Provincial Hospitals' Trust report[2] is that child guidance should be undertaken at centres controlled by the education authority, where mainly educational problems would be dealt with by a psychologist, and from which children deemed to be psychiatrically ill would be sent to clinics under the health authority, where a psychiatrist would preside. With its obvious administrative convenience, this proposal is approved by some educationists and mental-hospital authorities, but it is opposed by the Child Guidance Council (now merged with the National Association for Mental Health), which stands for the team principle. Objections raised to the scheme are that, in applying the ominous political device of partition, it depends for success on a mutual tolerance not always evident except where the working bond is close, and that it presupposes among educational psychologists a state of clinical experience which seldom exists: it entrusts to untrained persons the difficult task of recognising psychiatric illness among school-children, while the psychiatrist, against the trend of modern psychiatric practice, retreats once more to his clinical castle. Although this does not apply to the authors of the present proposals, similar schemes in the past have derived some support from a refusal to recognise the full implications of emotional disturbances in children, with a consequent desire to establish a cordon sanitaire to protect maladjusted children from psychiatrists unless all else fails This may even take the form of a standing committee whose function is to review reports from all possible sources before agreeing to send a child to a clinic. Another escapist argument is that most children's maladjustments may be satisfactorily dealt with by the light of nature and that psychotherapy is little more than applied common sense. But common sense, and persuasiveness, are common among those who handle children, and they will continue to fail where it is necessary to face the deeper emotional issues.

At first sight, the obvious place for child psychiatry is with the mental-health services; but child guidance is far wider than child psychiatry, and even the latter has derived comparatively little from the study of adult problems. Again, public opinion is not such that the prevention of children's maladjustments will thrive on close identification with adult psychiatry; the change in name from Mental Hospital Services to Mental Health Services has yet to be associated with an equal change in orientation, and mental hospitals have contributed little to the understanding of the difficult child. Recent experience, moreover, has shown that psychiatry is most effective when nearest to the problem as it occurs in life. Modern child guidance comprises work in maternity and child-welfare clinics; in schools, by selection and grading of pupils and by special teaching methods; in foster-homes, boarding homes, and residential schools; in children's hospitals, notably orthopædic and fever; and finally in diagnosis, disposal and treatment, at the clinic itself, in work in the home, and in the provision of special hostels for treatment. The authorities concerned in all this will include regional hospital boards, local health authorities, local education authorities, and the Home Office, and we should recognise that the first-named has no pre-eminence of interest: indeed the highest common factor, as it were, is the local education authority, which of all public bodies now has far the most intimate concern for the mental and physical development of children between the ages of 2 and 18. It seems logical, therefore, for the great preventive mental-health service of childhood to remain an integral part of that system, and there seems to be no paramount administrative reason for changing the existing arrangements by which child guidance is administered by the School Medical Service, which is itself intermediate between the education and the health interests. Thus placed, the child-guidance services can be linked through the School Medical Service with hospitals and specialists, and particularly with pædiatrics; and there is no reason why the psychiatrists employed in this work should not be carried on the establishments of regional hospital boards Both the medical and the educational aspects of child guidance should be under the unified control of experienced clinicians, and the operations of educational psychologists in the schools should be firmly based on the clinical team; though this does not mean that the psychiatrist must necessarily be the administrative head of the service. In addition there is every reason for general and psychiatric hospitals to develop their own departments of child guidance so that psychiatric principles may permeate medical teaching, so that research can be undertaken, and so that patients can readily be given any special form of treatment they may require.

Despite the demand, however, there may be no future in this country for child guidance unless the supply of clinically trained workers of all disciplines is radically increased. This is not a matter of giving courses of lectures and of amending the regulations for diplomas, but of providing clinical experience in therapy under the supervision of those who are qualified to teach. Concentrated courses of a few months give time neither to absorb the subtleties of treatment nor to learn about children at home and at school. Diagnosis and disposal can be learnt fairly easily, but to acquire therapeutic skill needs long-continued practice under supervision In the shortage of adequately trained therapists, competent and willing to treat difficult cases, lies the most dangerous threat to child guidance.

1. Blacker, C. P. Neurosis and the Mental Health Services, London, 1946.
2. Appendix to a report on the planning of hospital services in the Berks, Bucks, and Oxon region, Nuffield Provincial Hospitals Trust, 1947; see *Lancet*, 1947, i, 421.

recorded is 170 mm. Hg, while the lowest diastolic pressure is 100 mm. Hg. Of the 116 patients in the series, 78 had essential hypertension (61 benign, 17 malignant), 4 were probably examples of benign essential hypertension, and 18 had secondary hypertension ; in the remainder the cause of the raised blood-pressure was uncertain. The cases were divided into four groups according to family history : group 1 comprised those n which one or more parents had hypertension ; group 2 hose in which there was a probability of this ; group 3 hose in which there was no definite evidence one way r the other : and group 4 those in which the evidence was against hypertension in either parent. The control roup consisted of 71 unselected patients over the age of hirty with no history of hypertension. Analysis showed hat in approximately 76% of cases of essential hyper-ension there was a family history suggestive of hyper-ension, while in only 6·4% was the family history egative. In the 38 patients with secondary hypertension family history of hypertension was obtained in only 4%, and there was no evidence of such a history in 42%. he corresponding figures for the control patients over he age of forty were 36% with, and 35% without, a mily history of hypertension. As Platt points out, if sential hypertension is inherited by a simple mendelian minant transmission, family history should always be sitive. He has therefore reviewed the 5 cases in which mily history was apparently negative, and in only of these was it impossible to find some factor which rew doubt on the diagnosis of essential hypertension. hilst absolute evidence is still lacking, this investiga-on, particularly when taken in conjunction with the dings of Ayman[10] and of Weitz,[11] goes far towards tablishing the hypothesis that essential hypertension a hereditary disease conveyed as a mendelian dominant ith a rate of expression of more than 90%. Whether e inherited factor is specific for hypertension or is erely a tendency to arteriolar change is a question quiring further investigation.

STREAKY BLOOD FILMS

It is a sad fact that human curiosity is least stimulated the things which happen most often. There are, for stance, so many blood films in the hæmatologist's life at he accepts their physical vagaries with automatic ritation. The well-known product consisting apparently a “ drop of semi-clotted blood worried across the dirty rface of one slide by the jagged end of another ” he htly ascribes to bad technique, but the strange pre-lection of the polymorphonuclears for the edges of the m he regards with resignation. It is refreshing, there-re, to find Boveri, Waterfield, and Newman, whose eliminary report appears in this issue, tackling scien-fically that other familiar annoyance, the blood film hich, despite immaculate technique, dries in streaks. n coming to grips with this problem they were at first pressed by a correlation between such streakiness and high erythrocyte-sedimentation rate of the blood from hich the films were made. However, rouleaux did not cessarily occur in the ridges of red cells forming the reaks, and not all patients with a high E.S.R. showed the enomenon, in spite of obvious rouleaux in their films. urther investigation revealed the probable causal factor a raised blood-fibrinogen level, which often, but not ways, accompanies a raised E.S.R. Blood films in such nditions as uncomplicated anæmia or myelomatosis, which the fibrinogen content is normal but the E.S.R. ised, showed no streakiness. The obvious possibility at the ridges were due to some partial or impending agulation of fibrinogen was ruled out by the occurrence streakiness in oxalated or citrated blood. Moreover, the addition of traces of bile-salts, with a consequent lowering of the surface tension, abolished the ridges. It was finally observed that films made from plasma alone showed a wavy surface when examined while still wet if the plasma was derived from blood giving streaky films, while serum always produced smooth films.

The streaky film is of clinical importance since it may afford a simple and rapid method of demonstrating a significant increase in blood-fibrinogen, which, unlike the E.S.R., is not affected by anæmia. These observations of the physical behaviour of fibrinogen under certain conditions of concentration and surface action may also throw light on the more academic problems of blood-clotting. Finally there is the moral that an insatiable curiosity about the common little events of everyday life is a gift valuable to the systematic investigator.

BOVINE TUBERCULOSIS

THE present organisation of our universities, and of our local and national services, does not favour close collaboration between the medical and veterinary *professions: in spite of occasional exhortations about* the importance of comparative pathology, it is an unfortunate fact that medical and veterinary pathologists usually work quite separately. It is therefore all the more encouraging to find someone who has taken the lesson to heart and has endeavoured, in a subject of such major interest as bovine tuberculosis, to make a comparative study of the disease in man and cattle, and to present his results in the form of a comprehensive and eminently readable review.[1]

Mr. Francis has collected information from many different countries, and has provided useful figures on the incidence of tuberculosis in cattle and on the extent to which control measures have proved effective. He suggests that, in Great Britain, tuberculosis did not become common among cattle till the introduction of town dairies, which developed with the growth of the manufacturing centres during the latter part of the 18th century. The conditions under which the animals were kept in these dairies were deplorable, and it is not surprising that by the middle of the 19th century about 20% of cattle examined in Durham were found post mortem to be tuberculous. The most recent figures, based on tuberculin tests, lead to the conclusion that about 20% of all *cattle* in England, 7·5% in Wales, and 14% in Scotland are infected with the tubercle bacillus. For Great Britain, as a whole, about 17–18% of *cattle* and 30–35% of *dairy cows* react to the tuberculin test. The incidence of udder tuberculosis is estimated to be about 0·5% for all cows and 1·5% for tuberculous cows. There is reason to believe that the incidence of bovine tuberculosis has altered little during the last fifty years. The economic loss due to this disease in cattle alone is estimated to be £1–3 million per annum.

Contrasting the disease in man and animals, Francis points out that infection of cattle is mainly aerogenous and affects primarily the lungs, whereas infection of man with the bovine type of bacillus is mainly attributable to drinking milk and affects primarily the extra-pulmonary tissues. Except in infants, tuberculous infection of man results usually in a lesion that retrogresses and eventually heals. In cattle, on the other hand, infection, once it has occurred, tends to be progressive. Hence a positive tuberculin reaction is of far greater significance in cattle than in man. Indeed, Francis says that, since pulmonary lesions in cattle seldom heal, and since they usually extend by the

Rickettsial Pox

During the summer of 1946 an outbreak of an unusual infection occurred among the 2000 inhabitants of a housing estate in one of the boroughs (Queens) of New York City and was investigated jointly by the New York Department of Health and the U.S. Public Health Service. Although cases were noted sporadically in the early months of the year, it was not until July that the outbreak reached such proportions as to attract special attention. During the first six months of 1946 there were 124 recognised cases (6·2% of the total population), distributed over a wide age-group (from three months to seventy-one years); males and females were affected equally and no occupational relationship could be established.

Clinically [1] the infection was characterised by a primary skin lesion in the form of a papule; this soon developed into a deep-seated vesicle with surrounding erythema and later shrank to a black eschar which disappeared after about three weeks, leaving in most cases a small scar. The lesion was usually found on some covered part of the body and was often accompanied by some regional adenitis but no lymphangitis. About a week after the appearance of the initial lesion an acute febrile illness began, with fever, chills, sweating, headache, and backache—not unlike an influenzal attack but accompanied at the onset or within two days by a maculopapular rash which a day or two later became vesicular and then crusted and which disappeared in four to seven days without scarring. The intensity and distribution of the rash varied considerably, lesions being sparse to abundant and appearing sometimes on the limbs and sometimes on the trunk, but never on the palms or soles. The patients were not acutely ill; they remained alert and coöperative and showed little loss of appetite. There were no distinctive physical signs apart from the rash, and all the patients recovered without complications. Blood-culture and the usual serological tests were all negative; 21 out of 22 patients on whom blood-counts were done showed a leucopenia. The disease most resembled chickenpox and was so diagnosed initially, but the deep-seated vesicle and the lack of any characteristic distribution of the rash, together with the greater constitutional upset and the wide age-distribution, served to distinguish it. Specimens of blood from 15 patients were inoculated into animals, and from 1 out of 5 mice which received blood taken from a patient on the second day of fever an organism with the morphological, cultural, and staining characteristics of a rickettsia was isolated.[2] This rickettsia after primary isolation produced lesions in the guineapig, including well-marked scrotal reactions. It also produced lesions in the chick embryo, and an antigen prepared from the infected yolk sac was used to demonstrate the presence of complement-fixing antibody in the sera of convalescent patients: the same sera reacted less strongly with a Rocky Mountain fever rickettsial antigen. This serological cross-reaction, together with its behaviour in the chick embryo and the guineapig, suggested a relationship between the new rickettsia and *R. conori*, the causal agent of fièvre boutonneuse, but there seem to be some clinical and serological differences between the two infections.

Meanwhile the epidemiologists were establishing the source of the infection.[3] The only insect or animal parasites that were noticeably present in the infected blocks of houses were mosquitoes (*C. pipiens*) and mice. The mosquitoes were exonerated. The mice, it was discovered, were breeding in the basement incinerators, which for want of sufficient attendants were not being regularly fired and were therefore collecting refuse on which the mice fed and bred and from which they invaded various apartments. At the same time mites, often gorged with mammalian blood were discovered, sometimes in great numbers, on the mice, on the walls of the incinerators, and in various living-rooms. From two pools of these mites the same rickettsia—now called *R. akari*—was isolated, and it was also demonstrated, together with specific antibody to it, among the mice.[4] There was a good correlation between mite infestation and clinical cases of rickettsial pox in the houses that were carefully examined. The mite is probably the natural vector of this new rickettsia, and the mouse is the usual animal reservoir; but obviously when occasion offers the mite and the rickettsia are prepared to venture into pastures new, and so another rickettsial infection has been born.

Annotations

HYPERTENSION AND HEREDITY

Clinicians have long been convinced of the significance of a positive family history in assessing the prognosis of patients with hypertension. Hitherto this has been little more than a clinical impression, though it is more than fifty years since Riva-Rocci[5] published his article on sphygmomanometry, and forty years since Gibson[6] made his classical report on the same subject. Three factors may be held mainly responsible for this anomalous state of affairs. In the first place, only of late years has there been anything like agreement on what constitutes hypertension, and even today the agreement is almost as tenuous as that of a council of foreign ministers. The second factor is our lack of knowledge concerning the ætiology of essential hypertension, and the consequent inclusion under this generic title of a variety of conditions which are only now being gradually sorted out. For example, the importance of renal disease, apart from nephritis, has only recently been appreciated: Weiss and Parker[7] have claimed that at least 15–20% of cases of so-called malignant hypertension are due to chronic pyelonephritis, whilst Wosika and Maher,[8] by urological investigation, found that among 600 cases of hypertension 29% were secondary to demonstrable renal causes. The third factor is the difficulty of obtaining an adequate and reliable family history.

It is thus clear that any attempt to establish statistically a hereditary factor in hypertension is fraught with pitfalls, and Platt[9] was undoubtedly right to study a series small enough for personal investigation, and yet large enough to permit of statistical analysis. Only patients with symptoms referable to hypertension were included in his series; the lowest systolic pressure recorded is 170 mm. Hg, while the lowest diastolic pressure is 100 mm. Hg. Of the 116 patients in the series, 78 had essential hypertension (61 benign, 17 malignant), 4 were probably examples of benign essential hypertension, and 18 had secondary hypertension; in the remainder the cause of the raised blood-pressure was uncertain. The cases were divided into four groups according to family history: group 1 comprised those in which one or more parents had hypertension; group 2 those in which there was a probability of this; group 3 those in which there was no definite evidence one way or the other; and group 4 those in which the evidence was against hypertension in either parent. The control group consisted of 71 unselected patients over the age of forty with no history of hypertension. Analysis showed that in approximately 76% of cases of essential hypertension there was a family history suggestive of hypertension, while in only 6·4% was the family history negative. In the 38 patients with secondary hypertension a family history of hypertension was obtained in only [illegible]%, and there was no evidence of such a history in 42%. The corresponding figures for the control patients over the age of forty were 36% with, and 35% without, a family history of hypertension. As Platt points out, if essential hypertension is inherited by a simple mendelian dominant transmission, family history should always be positive. He has therefore reviewed the 5 cases in which family history was apparently negative, and in only [illegible] of these was it impossible to find some factor which threw doubt on the diagnosis of essential hypertension. Whilst absolute evidence is still lacking, this investigation, particularly when taken in conjunction with the findings of Ayman[10] and of Weitz,[11] goes far towards establishing the hypothesis that essential hypertension is a hereditary disease conveyed as a mendelian dominant with a rate of expression of more than 90%. Whether the inherited factor is specific for hypertension or is merely a tendency to arteriolar change is a question requiring further investigation.

STREAKY BLOOD FILMS

It is a sad fact that human curiosity is least stimulated by the things which happen most often. There are, for instance, so many blood films in the hæmatologist's life that he accepts their physical vagaries with automatic irritation. The well-known product consisting apparently of a "drop of semi-clotted blood worried across the dirty surface of one slide by the jagged end of another" he rightly ascribes to bad technique, but the strange predilection of the polymorphonuclears for the edges of the film he regards with resignation. It is refreshing, therefore, to find Boveri, Waterfield, and Newman, whose preliminary report appears in this issue, tackling scientifically that other familiar annoyance, the blood film which, despite immaculate technique, dries in streaks. On coming to grips with this problem they were at first impressed by a correlation between such streakiness and a high erythrocyte-sedimentation rate of the blood from which the films were made. However, rouleaux did not necessarily occur in the ridges of red cells forming the streaks, and not all patients with a high E.S.R. showed the phenomenon, in spite of obvious rouleaux in their films. Further investigation revealed the probable causal factor as a raised blood-fibrinogen level, which often, but not always, accompanies a raised E.S.R. Blood films in such conditions as uncomplicated anæmia or myelomatosis, in which the fibrinogen content is normal but the E.S.R. raised, showed no streakiness. The obvious possibility that the ridges were due to some partial or impending coagulation of fibrinogen was ruled out by the occurrence of streakiness in oxalated or citrated blood. Moreover, the addition of traces of bile-salts, with a consequent lowering of the surface tension, abolished the ridges. It was finally observed that films made from plasma alone showed a wavy surface when examined while still wet if the plasma was derived from blood giving streaky films, while serum always produced smooth films.

The streaky film is of clinical importance since it may afford a simple and rapid method of demonstrating a significant increase in blood-fibrinogen, which, unlike the E.S.R., is not affected by anæmia. These observations of the physical behaviour of fibrinogen under certain conditions of concentration and surface action may also throw light on the more academic problems of blood-clotting. Finally there is the moral that an insatiable curiosity about the common little events of everyday life is a gift valuable to the systematic investigator.

BOVINE TUBERCULOSIS

THE present organisation of our universities, and of our local and national services, does not favour close collaboration between the medical and veterinary professions: in spite of occasional exhortations about the importance of comparative pathology, it is an unfortunate fact that medical and veterinary pathologists usually work quite separately. It is therefore all the more encouraging to find someone who has taken the lesson to heart and has endeavoured, in a subject of such major interest as bovine tuberculosis, to make a comparative study of the disease in man and cattle, and to present his results in the form of a comprehensive and eminently readable review.[1]

Mr. Francis has collected information from many different countries, and has provided useful figures on the incidence of tuberculosis in cattle and on the extent to which control measures have proved effective. He suggests that, in Great Britain, tuberculosis did not become common among cattle till the introduction of town dairies, which developed with the growth of the manufacturing centres during the latter part of the 18th century. The conditions under which the animals were kept in these dairies were deplorable, and it is not surprising that by the middle of the 19th century about 20% of cattle examined in Durham were found post mortem to be tuberculous. The most recent figures, based on tuberculin tests, lead to the conclusion that about 20% of all *cattle* in England, 7·5% in Wales, and 14% in Scotland are infected with the tubercle bacillus. For Great Britain, as a whole, about 17–18% of *cattle* and 30–35% of *dairy cows* react to the tuberculin test. The incidence of udder tuberculosis is estimated to be about 0·5% for all cows and 1·5% for tuberculous cows. There is reason to believe that the incidence of bovine tuberculosis has altered little during the last fifty years. The economic loss due to this disease in cattle alone is estimated to be £1–3 million per annum.

Contrasting the disease in man and animals, Francis points out that infection of cattle is mainly aerogenous and affects primarily the lungs, whereas infection of man with the bovine type of bacillus is mainly attributable to drinking milk and affects primarily the extrapulmonary tissues. Except in infants, tuberculous infection of man results usually in a lesion that retrogresses and eventually heals. In cattle, on the other hand, infection, once it has occurred, tends to be progressive. Hence a positive tuberculin reaction is of far greater significance in cattle than in man. Indeed, Francis says that, since pulmonary lesions in cattle seldom heal, and since they usually extend by the bronchial route, nearly all tuberculin-positive animals may be regarded as infective for others. In the control of bovine tuberculosis, he believes that pasteurisation of milk affords the only hope of immediate benefit to the human population, and that the eradication method based on the tuberculin test is the only satisfactory policy for dealing with the disease in cattle. He draws attention to the fact that, except for tuberculosis, Great Britain has led the way in stamping out the major zymotic diseases of animals—rinderpest, pleuropneumonia, sheep-pox, rabies, and glanders—and he thinks that the time has now come to make a determined attempt to get rid of tuberculosis. If the rate of progress reached just before the war in the eradication scheme is maintained, he estimates that all British cattle will be in attested herds in about 40 years' time.

STAIN REACTIONS IN ERYTHROID CELLS

The visible changes in the reaction to various stains are everywhere used to differentiate cells and to assess the stage of their development. There is today general support for a modified monophyletic view of blood-cell development, postulating that most, but not all, cells derive from a common basophilic precursor, the hæmocytoblast. In erythroblasts, whether normal or pathological, the original basophilia of the cytoplasm pales as development proceeds, and then changes, through grey-blue stages, to the pink of the erythrocyte. The nucleus has nucleoli in the earliest (pro-erythroblast) stage, but loses them in the later stages. During the final collapse and pyknosis of the nucleus separated fragments often appear while the nucleus is still present, and many persist as inclusion or Howell-Jolly bodies after the nucleus itself has entirely disappeared.

New light on both the disappearance of cytoplasmic basophilia and the nature of the so-called inclusion bodies has been provided by the use of recently developed cytochemical techniques. Brachet[1] described a cytochemical test for ribonucleic acid which depends on the use of a ribonuclease discovered by W. Jones in 1920 and further explored by Kunitz.[2] The enzyme depolymerises ribonucleic acid, but has no action on deoxyribonucleic acid; and it is the latter which is responsible for the Feulgen reaction that stains nuclear chromatin. Brachet found that the basophilia of the young cells in the bone-marrow of various animals was removed by ribonuclease, and he deduced that the presence of ribonucleic acid accounted for the tint. This reaction has been applied by White[3] to human bone-marrow material, both normal and pathological, obtained by sternal puncture. The marrow films are fixed with Susa solution and then stained with pyronin-methyl-green; this colours bright red the cytoplasm that appears basophilic with the usual Leishman or Jenner-Giemsa stain, and the degree of red stain corresponds to the deepness of the basophilia; the stain also colours nucleoli red. The chromatin of the nucleus takes up the methyl-green. Hæmocytoblasts and all early erythroblasts show red-staining cytoplasm and nucleoli when present. If the marrow films are exposed to the action of ribonuclease before staining, then the nucleoli and the cytoplasm fail to take the pyronin stain. Early normoblasts and megaloblasts show decreasing basophilia as hæmoglobinisation increases; this is paralleled by a decrease of the pyronin-staining material that is removed by ribonuclease. There is thus good evidence that the cytoplasm of early erythroblasts contains ribonucleic acid, and that this is the substance responsible for their basophilia. As development proceeds, ribonucleic acid becomes less and hæmoglobin increases in the cytoplasm, these two changes being reflected in the change from basophilia through pol chromatic stages to the pink colour of the mature r cell. Myeloblasts can also be shown to contain rib nucleic acid in their cytoplasm, and the concentrati decreases as the cells mature into myelocytes.

La Cour[4] has applied the Feulgen reaction f deoxyribonucleic acid to dividing erythroblasts seen the bone-marrow of patients with pernicious anæmia. I noted that the chromosomes of pro-myelocytes have on a low charge of deoxyribonucleic acid as compared wi the pro-erythroblasts. There were other mitotic abn malities, and La Cour suggested that the granulocy abnormalities in pernicious anæmia might be due to t lack of deoxyribonucleic acid because the pro-eryth blasts take the lion's share of a short supply. This interesting, and it links up with the suggestion that fo acid is concerned with nucleic-acid metabolism. B La Cour's observations were made on 2 patients on and it is not clear that the different kinds of cells we adequately differentiated; nor were hæmoglobinis megaloblasts seen in mitosis.

The fact that inclusion bodies are sometimes to found in red blood-cells has been known for a long tim and it was also known that they were particularly lial to appear and persist after splenectomy or even atrop of the spleen. These were the Howell-Jolly bodie they stained a reddish-purple with Leishman or Giem which distinguished them from the grey or black dots punctate basophilia. The Feulgen reaction shows th the Howell-Jolly bodies are nuclear fragments; t bodies of punctate basophilia are not. In 1945 Pappe heimer and others[5] reported the appearance of inclusi bodies in the red cells of 3 patients whose spleens had be removed for anæmia of probable hæmolytic type. T bodies were rounded and often multiple; they did n give the Feulgen reaction and so were not Howell-Jol bodies. They did react with potassium ferricyanide an hydrochloric acid, thus showing that they contain iron. Now iron-containing erythrocyte inclusions h been described by Grüneberg in mice and human subjec and named "siderocytes"; they were thought to be r cells nearing the end of their life, with free iron alread splitting off from the hæmoglobin. Pappenheimer an his colleagues thought that their cells might well l siderocytes, but they offered no explanation for the appearance. Recently McFadzean and Davis[6] in Gla gow have reported iron-staining erythrocyte inclusion in patients with acquired hæmolytic anæmia, and th number of affected cells rose to 60–80% after splenectom These bodies gave reactions like Pappenheimer's bodies they were Feulgen-negative but gave a positive iro reaction; they were mostly rounded but some ha bizarre shapes and were quite large. Investigation of th marrow showed that normoblasts, even when not full hæmoglobinated, were affected; sometimes 70–80% of these cells contained inclusions. It was noted, too that the proportion of normoblasts with cytoplasmi inclusions was about the same before splenectomy a after. McFadzean and Davis therefore suggested tha the red cells deriving from affected normoblasts ar unusually susceptible to destruction in the spleen and that splenectomy enables many more of them t survive in the peripheral blood-stream. They also think that affected red blood-cells in their patients resembl Grüneberg's siderocytes, but hold that interference wit hæmoglobin *anabolism*, rather than breakdown, i responsible for their appearance. These recent reports suggest that some of the earlier descriptions of Howell-Jolly bodies increasing after splenectomy really referred to those ferruginous non-nuclear bodies. Their significance

THE PROBLEM OF GASTRIC CANCER

Alan Shorter
M.B. Sydney, F.R.C.S.
E.M.S. SURGEON, MOUNT VERNON HOSPITAL, NORTHWOOD, MIDDLESEX

Despite encouraging progress in dealing with cancers in more superficial and accessible sites, cancer of the stomach remains a desperate problem for the clinician and desperately fatal for the victim.

Though the total incidence of cancer is believed to be about the same in the two sexes, in the rich and the poor, and in all nations, gastric cancer has sex, social, and racial distinctions. The racial incidence varies from 20% of all cancers in Great Britain to about 40% in America and over 50% in some Continental countries.[22] It is much commoner in the poor than the rich, and the preponderance of males is 3 : 1 in America and 4 : 3 in Britain. But in all civilised countries where records are kept it is seen to be the chief cause of death from cancer, being responsible for 13,000 deaths annually in Great Britain, and about 40,000 in the U.S.A.[46]—i.e., 33% of all cancer deaths.[29] Worse still, as Ogilvie[32] points out, its highest incidence in men and women is between the ages of 40 and 60, when they have established a place in life, a home, and a reputation; when they are most useful to their profession and their country, and most necessary to their families. It is the commonest type of cancer with the worst results from treatment, for on the average only 1–4% of all patients are alive after five years following curative surgery, and only about four months' prolongation of life can be obtained by palliative treatment.[27]

What can be done to decrease this toll of valuable lives? Apart from the possibility of prevention, about which we can do little until we know more of the causal factors, the problem is one of diagnosis and treatment. Early diagnosis is particularly important, for we know that most patients can be cured by radical surgery when the disease is localised to the stomach.[10] But at present some 80% of cases of gastric cancer are beyond any hope of cure by surgery alone when first brought to the surgeon.[30] In spite of the tremendous advances made in the surgical treatment during recent years, radical surgery can hardly become more radical. What of irradiation? Post-mortem findings show that over 20% of people dying of gastric cancer have the disease *still confined to the stomach* and immediately adjacent glands,[26] but the results of irradiation so far have been disappointing, though they should improve with the wider use of such methods as direct irradiation at high intensity.[12 13] This improvement may not be dramatic, however, and we are forced to conclude that improved results must mainly depend on getting more early cases to the surgeon, and so on earlier diagnosis.

REASONS FOR TOO LATE DIAGNOSIS

Why is diagnosis so often too late? The blame is shared by the patient, the general practitioner, and the consultant. At the New York Hospital it was found that the average duration of dyspeptic symptoms in a series of gastric cancers before admission for treatment was $12^1/_2$ months.[9] The patient took an average of 8 months to seek advice from his doctor, who then took an average of $4^1/_2$ months to reach a tentative diagnosis. Sometimes indeed there was a delay of 6 months or more in the outpatient department, *in spite of all the diagnostic aids*, before a diagnosis was made and surgical treatment sought.

Why should the patient hesitate *in seeking advice*? As Finch[14] says, the main reasons are ignorance, fear, false modesty, and gullibility. Gastric no definite and characteristic symptoms in the ea stages, and it is often only the onset of complicati that may arouse the patient's suspicions.[44] Inde many cases are devoid of symptoms until the diseas inoperable[30 36 43]; or symptoms may have been pres for a few weeks only, though the disease is much ol On the other hand, the recognition of vague sympto depends on the sensitivity of the patient, and in so people symptoms only become obvious when frequen repeated and gradually intensified. Gastric cancer beg in the stomach as a limited disease and may remain for a long time, with mild and hardly recognisa symptoms.[28] Curability depends on its recognition prompt surgical treatment during this stage. *But m* people consider a mild degree of gastric discomfort *be a part of the normal process of growing old,* indigestion or dyspepsia signifies to them an uncomfo able but benign process.[29] Patients generally will seek medical advice in the early stages of such va symptoms as loss of appetite, mild epigastric distress, slight loss of weight[38]; only too often they treat the selves for months with one or more of the many alkal panaceas, encouraged by the relief these often br even in gastric cancer. There is no part of his own someone else's body the average layman feels m competent to treat than the stomach, and no part the body where such interference so often leads to disas When finally he does seek advice, his doctor may pen with similar remedies and minor dietary restricti without proper investigation, until it is too late. B practices must be deplored. The advertising of dyspep cures to the public should be prohibited by law,[1] in Ogilvie's words[30] "alkalis are the undertaker's b friend." The tremendous sale of patent medici encourages self-diagnosis or chemist's diagnosis a treatment.[23] In about half the cases gastric cancer h spread beyond the stomach before pain and repeat vomiting occur, the common dyspeptic sympto bringing the patient to his doctor.[4] Pain and bleedi are the symptoms that bring the patient to his doct "at the double," and their absence *in the early stages* gastric cancer lull him into a false feeling of security

RE-EDUCATION

We must become more "cancer-minded."[33] Th means re-education of the general public and the medic profession as a whole to make them more canc conscious. For the layman, a nation-wide propagan campaign is badly needed, as carried out so successful in the U.S.A. and New Zealand. We must get rid of t paralysing fear of cancer, by emphasising the fact th early cancer can be cured. At present most people fe it is almost a death sentence to be told they have canc —as indeed it still is only too often. Unless and unt *we can hold out more hope of a cure,* patients will n present themselves freely for early diagnosis. When the do come along with vague dyspepsia, we must not laug at them or call them neurasthenic, but *must investiga* them thoroughly. The usual objection to educating t lay public is that it will produce neurotics and introvert who will inundate the medical profession with their sil or imaginary complaints. But neurotics are born, n made, and they flourish more readily in an atmosphere ignorance and superstition. We must remove by educa tion the reasons for not seeking advice early—ignoranc fear, false modesty, and quack remedies. We ne propaganda to counteract the inherent tendency of peopl to treat and palliate their own digestive complaints.

Much could be done in the schools by instruction in th principles of human anatomy and physiology, togethe with simple rules for health. This should help to remov *the fantastic misconceptions* about the body and it care that still exist in most adult minds, often fostere [illegible] orant and prudish parents. Even as medica dents we are taught little about health and how to guard it. For adults, carefully worded and illustrated opaganda could be disseminated by the lay press and by emas as well as by radio talks. It must be cunningly nuated into the usual entertainment. Special lectures publications usually have too limited an appeal to ch many people. The gist of the propaganda should to encourage people to avoid seeking advice from their ghbours or the chemist, but to go straight to their ctor when they notice any untoward symptoms, which ld be indicated briefly. It must emphasise the fact t even slight symptoms may sometimes be serious, t early diagnosis vastly increases the possibility of re, and that delay may be dangerous to oneself and se distress to other people.

As regards the medical profession, it is a depress- g thought that most of our teaching and clinical perience is with inoperable gastric cancer. Teaching ll be vain if it does not help us to diagnose the disease rlier while still operable.[9] It is relatively unimportant patients that inoperable cancer can be diagnosed rectly. That can almost be done by the uninitiated, d it is too late to help much then! Most accounts in gical textbooks of the symptoms and signs of gastric cer are of the late and inoperable stages, since the rly stages have no definite and characteristic symptoms. st textbooks need to be rewritten in this respect. e average medical student is not much interested in ncer and its early diagnosis and treatment, not being are of the urgency of the problem. He will say there e many more exciting things to learn about, and e outlook is so hopeless anyhow—why can't we leave ch people to die in peace? This defeatist attitude is e result of our medical educational system, which is lly in need of drastic revision. Had the pioneers of our ofession thought likewise of the other diseases—e.g., berculosis, syphilis, and smallpox—we would still be the dark ages of medicine. We are still in the dark ages the diagnosis and treatment of gastric cancer.

INVESTIGATION

Alertness of the patients to the vague early symptoms, d careful assessment of them by the medical profession, e the chief means of early diagnosis. Many doctors o not fully appreciate the need for thorough investiga- on at this stage. Early diagnosis is difficult and rare inly because cancer is never suspected then. Anyhow, st doctors feel that the prognosis is so bad that they ll not urge reluctant patients to undergo investigation, nd thus the time is missed when a cure might well be ssible. But if they felt that once a cancer was diag- osed it could be cured, their whole attitude would hange. Before any progress is possible we must break his vicious circle.

Early diagnosis needs not casual and superficial ttention but eternal vigilance. More mistakes are made hrough not looking than not knowing. Generally peaking, at present we are not making the best use of he diagnostic aids available. Mullen [29] has divided hysicians into two classes—those who always suspect stric cancer and never find it; and those who never spect and always miss it. The first complain of the tility of their efforts; the second of the hopelessness f the disease. To the suspicious physician the present iagnostic methods suffice for very many more patients han those to whom they are applied. Gastric cancer is ways later than you think, and any delay in diagnosis ssens the patient's chance of having the only known ethod of cure—surgery. Instead of being thought of last, r often not at all, gastric cancer should be thought of first n the diagnosis of every dyspepsia, irrespective of age.

Physicians, who usually see the patients first, cannot xpect surgeons to improve the outlook of gastric cancer rely by further improvement in surgical technique. Allen [1] has shown that, at the Massachusetts General Hospital, though the resectability-rate increased from 27% in 1933 to 37% in 1939, and the operative mortality decreased from 38% to 25%, the five-year cure-rate rose only from 20% to 21%. So, with increased courage and skill on the part of surgeons, more patients were operated on and survived operation but there was no appreciable increase in cure-rate. Only when a greater proportion of operable cases are brought to the surgeon will more cures be effected by surgery alone. Hence earlier diagnosis is the crux of this problem.

This is the psychological age in medicine. Only too often our patient's symptoms are classed as neurotic or functional, if a possible or likely cause is not found easily on examination and investigation, which is often superficial and incomplete. Many patients have been sent to the psychiatrist because of such a failure to diagnose the disease. Assuming that every possibility of physical disease has been eliminated, he can always find some kind of psychic trauma to explain the symptoms. (Who has not suffered some psychic trauma at some time?) So patients have been treated with hypnosis, narco-analysis, or even continuous narcosis instead of radical surgery, which has not been sought until the true diagnosis was only too obvious. The more often a genuine disease is thus misdiagnosed and wrongly treated, the more likely is the patient's behaviour to become hysterical and exaggerated, like that of someone about to be buried alive. Each time he sits up to protest he is alive, he is pushed back with the assurance he is dead and about to be buried! Let us not be too impatient to dismiss our patient's complaints as neurotic, but rather search more patiently and diligently for the cause if it eludes us at first. Even neurotic patients may develop physical diseases, including carcinoma of the stomach, though their dramatic description of their symptoms may contrast with the paucity of their physical signs.

Radiography and Gastroscopy

Too late diagnosis may be due to the diagnostic methods we use or, more likely, to our interpretation of them. It is now well recognised that radiography and gastroscopy together are essential and complementary investigations for gastric cancer,[11] but they are not used together sufficiently often when cancer should be suspected. Though neither is infallible and each has its shortcomings, a combination of both will give a higher number of correct diagnoses than will either method alone.[38 39 41] Moreover the radiologist and gastroscopist must be expert, thorough, and persistent, for though the diagnosis of late cases only confirms the clinician's opinion and is easy, the diagnosis of early ones may confirm a mere clinical suspicion and is highly skilled and difficult.[29] In expert hands these methods are nearly always accurate, but in other hands they can be dangerously misleading.[16]

By gastroscopy, with adequate preparation and premedication together with careful and gentle instrumentation, it is nearly always possible to examine the whole stomach. Correct interpretation of the findings is far harder and requires careful observation and long experience, as well as correlation of the findings with those of the radiologist, the surgeon, the microscopist, and even the pathologist at autopsy. Gastroscopy is most useful in helping to decide between simple and malignant ulcers.[3 38] Some cancers are not seen by gastroscopy (1) because gastroscopy is impossible, as in cardiac obstruction by the tumour, or leather-bottle stomach which cannot be distended with air to give a good view, and (2) because the tumour is hidden in one of the blind areas found in some stomachs. As regards gastroscopic biopsy, we have as yet no instrument with which this can be performed safely and easily. But even biopsy is not always reliable, especially when negative; and, since the degree of cellular differentiation may vary from place to place in a tumour, the value of a single biopsy is problematical.[40] If less reliance were placed on radiological findings, especially when doubtful or negative, and if gastroscopy by an experienced observer were included in the routine investigation of all dyspepsias, we should diagnose more early cancers.

Some cancers, especially early ones, will not be found by radiography at the first or even subsequent examinations. The method fails most often in ulcer-cancer, where sometimes only a pathologist can tell the simple from the malignant ulcer.[15 45] The radiologist must be persistent: a single negative result must not lull him, the patient, or his doctor into a false sense of security; and if the symptoms continue the examination must be repeated frequently, preferably by the same expert. Minor but constant defects in peristalsis, due to infiltration of the submucosa, may be seen by radiography. Ledoux-Lebard[24] uses many rapidly taken or superimposed films to show obliteration of rugæ, changes in the mucosal pattern, and persistent defects in peristalsis. Gross filling defects due to ulcer or tumour are easily detected, but they are not due to early cancer.[29]

Radiography will give good results only if the mucosal-relief technique with compression and spot films, combined later with complete filling of the stomach, are used.[38 41] The mucosal-relief technique[3] shows fine details of the mucosal pattern, and spot films[21] permit recording of any phase of the radiographic examination without interrupting the screening. (This last is used to study gross details and for aiming the machine in taking spot films, which give a permanent record with finer detail.[6]) It must be constantly remembered that, taken generally, positive findings on radiography are reasonably reliable, but negative results may be dangerously misleading. Cooper[9] reports a correct radiological diagnosis in 70% of cases at the first examination, increased to 90% after repeated examinations. But this diagnostic accuracy is offset by the fact that 85% of these cases were hopelessly inoperable, and it would probably be much less accurate in earlier cases. As Wangensteen[44] has put it, too many doctors are credulous enough to accept the opinions of the radiologist as though he wielded an infallible divining-rod; whereas overwork and poor equipment may make him little more reliable than a crystal-gazer. There is a need of many more radiologists trained in the latest methods of gastric examination, and for great improvement in radiological equipment. This should include spot machines and tilting tables, and might well provide for a ciné-film record of all screen examinations of œsophagus, stomach, and duodenum.

Gastric Acidity

Gastric-acidity estimation is helpful provided the total response to histamine is estimated.[10] Results are fairly constant, for Polland[34] found the acid below normal or absent in 85% of gastric cancers, and no case of hypoacidity in gastric ulcer. Allen[1] noted achlorhydria in 60% of malignant ulcers and said that malignancy was to be expected in the achlorhydric stomach though the presence of acid did not rule out cancer. Reid[37] and Brunschwig et al.[5] concluded that 60% of patients with gastric cancer have achlorhydria, and Mullen[29] found it in 70–80%, though he felt the presence of high acidity did not disprove cancer, especially with a prepyloric ulcer. Lewis[25] considered achlorhydria one of the most valuable early signs of malignancy, and Holman and Sandusky[20] held that low or absent hydrochloric acid remains the most reliable single piece of evidence of gastric cancer. Comfort et al.[8] have shown that the acidity is nearly always below normal in patients destined to develop gastric cancer, and that this low acidity develops early and persists.

Other Investigations

The many other investigations that may help u
diagnose gastric cancer include estimation of hæmogl
and blood-cell levels, erythrocyte-sedimentation
plasma-protein content, plasma and urine vitamin le
and liver-function tests.[35]

But too much reliance must not be placed on t
aids to diagnosis, especially when they conflict with
clinical suspicions, which should always be given
utmost consideration. Too many patients have lost
chance of life because a single investigation did
confirm the physician's suspicions of gastric ca
With persistence of symptoms, however vague, th
not sufficient reason (as Reid[37] says) for assuring
patient all is well and forgetting him. We may be w
in our suspicions; but, in the words of Ogilvie,[33] i
always wait until we are sure we are right, we
always be just too late to cure the patient. It mus
borne in mind that, though the highest incidenc
gastric cancer in women is between 40 and 50 years a
men between 50 and 60 years, this is not by any mea
disease of middle or old age, and anyone over 30 y
may be affected. Walton[43] and Ogilvie[30] say
dyspepsia developing in a person over 40 years, wit
any previous dyspeptic symptoms, is due to cancer
we have proved it otherwise.

Laparotomy

All competent authorities agree that, should
dyspepsia not respond to proper medical treat
within a few weeks, it should be fully investigated
the results are inconclusive or negative but the sympt
persist, the investigations should be repeated, and
*a laparotomy performed. To wait and see courts disas
far better to look and see. Though unnecessary operat*
are to be deprecated and should be avoided,[11] laparoto
is the best of all means of discovering the presenc
absence of gastric cancer. Then we are faced with rea
not merely shadows in a film. Exploration by a gas
surgeon should be safer than allowing the passag
time to decide the correct diagnosis (Wangensteen
A live mistake, says Ogilvie,[33] is better than a d
certainty, and there is more rejoicing in heaven
one negative laparotomy than over ninety-nine that
positive but too late.

SURGICAL TREATMENT

If the diagnosis is still in doubt even at laparoto
we must take what is the safest course for the patie
for our only chance of curing him is at the first gas
operation. So we must ensure that radical surgery
used whenever possible, not *only* in every proved
of gastric cancer but also in every case where it is e
suspected on exploration. If we do any less than t
we are not taking advantage of the best opportun
to cure the patient. The happiest way to diagn
gastric cancer is to be told by the pathologist after s
a gastrectomy: "That's a cancer, that was!"

So it is imperative that the surgical diagnosis a
treatment of gastric cancer should be left to prope
trained and competent surgeons. Nobody who is
able and willing to perform the most radical operat
possible should attempt to operate on a patient suspec
of having gastric cancer.[29] He must not rush in w
unseemly haste but must organise the whole procedu
like a general planning a campaign, paying due attenti
to adequate preoperative preparation and postoperati
care.[12 35 37 44] The operation must be planned to d
with the peculiar features and possible or actual spre
of the disease in each case. The experienced surge
will set out to remove the whole of the disease and w
decide on the best method of restoring the continui
of the alimentary tract after this has been done
he will not cramp the scope of his operation by so

received form of anastomosis, which might lead to failure to extirpate the growth completely. In outline operation should involve radical removal of the r and all the accessible potential field of spread, glandular and local, even in the absence of palpable . This is generally recognised as the best means ating operable cancer of the breast or colon.

Gastric cancer is likely to spread round the duodenum head of the pancreas, as well as along the left gastric ; hence these areas should always be dissected ely.[7, 30, 43] Failure to do this is often excused the absence of palpable glands, but it is really an plete attempt to eradicate all of the disease. many large glands are inflammatory, whereas many ones, even when impalpable, are neoplastic. microscopical section, and often even with cannot be certain whether a gland is involved growth. So the extent of the standard operation of gastrectomy for cancer should be increased than decreased.[1, 30] It may be impossible to clearly the actual extent of spread in the stomach and subtotal gastrectomy may divide an extension growth. In such a case total gastrectomy might the chances of cure, though the patient has a far more risky operation. When it seems to get clear of any extension of the growth in stomach or duodenal wall, radical gastrectomy[30, 31] give the best chance of cure.

authorities agree that surgery is always worth , except where there are clinically obvious wide- metastases. The desperate case (though not the one) is worth exploring, for laparotomy is the reliable way of deciding the correct form of treatment.[11] Gastrectomy may be undertaken as a curative or a palliative measure, and the criteria of operability with different surgeons.[11] Should curative radical ectomy be impossible, owing to irremovable local of the cancer or to the patient's poor general condition, direct irradiation at high intensity[12] may be . If this is impracticable, palliative gastrectomy, removing the primary lesion while leaving the more spread of the cancer, may increase the patient's without improving his prognosis. Apart from there are other less severe palliative operations, as gastric exclusion, gastrojejunostomy, gastrostomy, or jejunostomy, which may relieve suffering appreciably prolonging life. They may allow patient to put his house in order and make some for his family, and sometimes they lead to improvements in condition.[18] It is unjustifiable merely to close the abdomen when an inoperable found. By so doing, we fail in our primary duty patients—to alleviate suffering.[17]

ORGANISATION

The implementation of the Cancer Act, in conjunction the impending National Health Service, offers an unparalleled opportunity for improving the diagnosis and treatment of gastric cancer. Division of the whole country regions, each with its cancer centres for diagnosis, treatment, and follow-up, should enable all patients suspected of cancer to be examined, treated, and followed up by experts. This should be a great improvement on the present disorder, provided we make sure the "experts" are sufficiently trained and experienced in their specialty; but, as Finch[14] says, we must the development of the "cancer specialist" or "cancerologist." Further, the cancer centres must not up naked and unashamed, as long as people generally have such a fear of cancer, which still carries social stigma. They must be disguised by enveloping cloak of a general hospital, where the allied diseases of the same viscera can be with in each department. Having all kinds of dyspepsias, and perhaps other surgical conditions, mixed in a ward with gastric cancers is of inestimable value to all concerned. It helps the morale of the cancer patient to see others having operations and getting well; it helps preserve the mental balance, sanity, and cheerfulness of the doctors and nurses; and it reduces the difficulty of obtaining medical and nursing staff.

The danger of all this planning and organisation is the damping down of individual enthusiasm and initiative, with the development of mass-thinking, leading to a millennium of mediocrity. We must strive to preserve our freedom of thought and action, which must be coupled with a desire for genuine progress and an increase in knowledge. This will be achieved only by continually striving with humility and an inquiring mind. We must ensure that change means real progress, and that the welfare of the patient always remains the first consideration.

In the meantime while the "back-room boys" are working out new methods of treatment, and the planners are at work, we should try to make much better use of the methods of diagnosis and treatment available now. As has been said above, the present diagnostic methods are adequate for very many more patients than those to whom they are applied, and radical surgery can cure the large majority of patients with gastric cancer if carried out when the disease is localised to the stomach.[10]

RITISH EMPIRE CANCER CAMPAIGN

the annual meeting held in London on Nov. 26 H. the Duke of GLOUCESTER, president, said that lebration of the campaign's 25th anniversary next r a special appeal for funds will be launched. In the financial year the public, subscribed £135,000, not ding sums raised in the autonomous areas. This is highest figure yet reached, but does not permit the sary extension and intensification of the work.

rd HORDER, reporting as chairman of the Scientific sory Committee, said he felt more hopeful than r before about the results of cancer research and tment, and more certain of the service rendered by campaign. The problem is still the causation of er—not the cause, " for of causes of cancer we have dy an abundance." Any one of the many somewhat ted facts may prove a pointer. Planning is essential st the strategy and then the tactics. The 25th versary appeal will give the public an opportunity aking the programme which the campaign has in r a real and not a visionary one. It is an ambitious ramme, and very expensive, but vital in the public rest :

A special committee has been set up to develop research the whole virus position in relation to cancer. This ves the activation of several ad-hoc teams up and down country. A grant of £25,000 has already been set aside this research.

Travelling fellowships are imperative, with long-term ments of from five to ten years' duration, if the acute tage of workers is to be provided against.

The campaign requires another special committee set up ganise research on chemotherapy.

The new tools of atomic-energy physics must be made lable to B.E.C.C. workers.

Lastly there is great need of education with regard to er, both of the doctor and of the public. Thousands of are lost every year through want of diagnosis during the ble stage of the disease. Not only so, there is also the tion of prevention ; here there is more need for education.

THE MENTAL HOSPITALS

E annual report of the Board of Control[1] tells of nued overcrowding in our mental hospitals. At end of 1946 there were 146,444 people under care er the Lunacy and Mental Treatment Acts, 128,579 ese being in public mental hospitals. The total beds hese hospitals fall short of this number by some , and their numbers are further reduced—from such es as staff-shortage, need for restoration and re-equip- t, and diversion of beds to war-time casualties— ver 15,000. Thus overcrowding amounts to 13·1% the basis of recognised bed-space. More than half admissions in 1946 were of voluntary patients. al admissions showed an increase of 6009 over those 945—an increase due, the board feel sure, not to e in the incidence of mental illness but to a growing reness of the need for early treatment. They esti- e that during the next ten years an additional 1500 s a year may be needed ; and presumably they me that these will be in addition to existing idle diverted beds when these have been reclaimed for the tal hospital service.

he "most serious single handicap" under which the ice has laboured has been, and is, shortage of nursing f. By the turn of the year, it seems, some hospitals d the situation easing slightly, and many made use uxiliary staff—orderlies and the like—and of part- e voluntary workers from the British Red Cross ety and the Order of St. John, and from the Women's ntary Services. The practice of requiring nurses eep on the wards seems to be dying out.

he board note that the possibilities of occupational apy for patients with long-standing mental disorder not yet fully understood by many who work in pitals.

In England Now

A Running Commentary by Peripatetic Correspondents

THIS is no time for lightly proposing new textbooks and manuals, but I am worried about recently qualified men who don't understand what the patient says. Oughtn't there to be a glossary of lay terms for medical people; for remember the man who, when a patient told him she "hadn't seen anything for three months," sent her to the Eye Department? Does every new doctor realise that "tummy trouble," spoken of in an open and cheerful manner, means upper abdominal pain, whereas if there is a dropping of the voice and eyes it means diarrhœa? "Inside trouble," is always gynæcological, and to "have all one's inside out" is to have a total hysterectomy not a pan-evisceration. "Something coming down" is again usually gynæcological, but may occasionally be a thrombosed pile. Another point to remember is that the urinary bladder is rude and will be referred to in a shamefaced way as the waterworks, while the gall-bladder is a polite and interesting organ and can be discussed freely at tea-parties; and if a woman ruefully confesses that she has "fallen again," the doctor should not ask if any skin was knocked off. "Dizzy turns" and "blackouts," of course, may be anything, but usually after exhaustive investigations prove not to be epileptic attacks. In fact, anyone who has had to deal with soldiers will recognise blackouts as simple blackouts, and leave it at that.

The glossary should also deal with terms in use in various parts of the country. At my first outpatients in a Nottingham children's hospital the first mother complained that her child was "tissucky" and the second that hers was "mardy." The first child had a mild bronchitis; the second was fractious, bad-tempered, and generally difficult. Both lovely words but very confusing at first acquaintance.

* * *

Invited by the ever-attractive possibility of getting something for nothing, we found ourselves a week or so ago wandering through the doors of the London Medical Exhibition. As we stepped into the Odeon-like foyer we were eyed narrowly by a gentleman suspiciously demanding if we were "of the Profession." We reassured him with some disdain, adding in explanation of our immaturity and general untidiness that we were residents of St. Ethelred's. "Ah yes," he beamed at us, "most welcome, I'm sure. You will find the bar on the lower floor."

I am an experienced exhibition-goer, being educated all the way from the original Wembley extravaganza by way of the Ideal Homes, Radiolympia, the Motor Show, and the 1937 *Exposition de Paris*, to last year's Chelsea Flower Show. At all of these gatherings, with the understandable exception of the Flower Show, an exuberance of free samples was available to be carried away by the delighted visitors. I have left such affairs to find my pockets bulging with all sorts of junk from model rubber tyres and improved lavatory brushes to a free annual subscription to a society journal. The subsequent problem of finding what the hell to do with the collection appears negligible against the thrill of their costless acquirement.

The Paris exhibition was highly satisfying from the sampler's point of view, for the champagne and cognac stands cascaded their wares, and free bottles of Grand Marnier went along with buckshee crêpes suzettes. At the Horticultural Hall we had to content ourselves with jostling towards a salver of diabetic chocolate, a couple of diabetic rolls (no butter), a cup of baby food, some strained carrots, and what later turned out to be a handful of raspberry-flavoured laxative. In addition, we are now confidently expecting the daily arrival of small though gratuitous packages of malt drinks, phenobarbitone, nose-drops, hair-oil, and contraceptives.

As we wandered through this hippocratic bazaar we greatly enjoyed listening to an all-electric stethoscope and diathermying large slices from an appetising hunk of raw horse-meat. We were enchanted with an illuminated tableau of the internal workings of the halibut, and with a sort of radar screen ultimately attached to a frog's gastrocnemius. The corset-stand attracted our passing attention, the charming young lady who explained the mechanics of the apparatus appearing only slightly disappointed when we failed to place an order (there were no free samples). Several nearby stands advocated the waters and general social amenities of our British spas. In response to our mild inquiries an enthusiastic young fellow enlarged on the beneficial effects of these towns, in gratitude for which we allowed him to post on a wide selection of spa literature—giving the name of a member of the Ethelred's staff renowned as an incorrigible bon viveur.

The anæsthetic apparatus was worthy of its almost invariable appearance at some point in any recent British film. We have left the days of the rag-and-bottle so completely behind us that one feels self-conscious inducing anæsthesia with anything not resembling the front of a Buick, and of about the same price. The modern anæsthetic machine contains so many otherwise anonymous knobs labelled PRESS as to constitute an invitation to manslaughter for enthusiastic though inquiring anæsthetists like ourselves. We pressed a few knobs here and there, and were piqued when nothing seemed to happen. By that time we had goggled at the glittering machinery so long that we fully expected either Schenectady or a boiled egg to come out of the cabinet somewhere.

* * *

Ordinary associations of ideas are with the conscious rather than the unconscious content of the mind. A provincial psychiatrist, musing in Victoria Station, thought hardly at all of childhood fantasies of being an engine-driver, and still less of their possible origin in the desires to play clockwork trains on a vast scale, or to be grown-up, or in latent aggressive drives or what-not. He thought that the local departure boards read like a mental hospital directory, so many of the names being those of well-known mental hospitals. However, the provincial psychiatrist restrained himself from passing a devastating judgment on the mental health of the Metropolis by recalling that the number of mental hospitals in an area is an index, not of the amount of mental disease but of the adequacy of the hospital services.

* * *

An interesting study might be made of mass-psychology in relation to sport and the almost hysterical excitement which may be provoked by the sporting party-spirit. The enthusiasm which used to be limited to the village green is now extended (by cable and wireless) to the ends of the world, and for days before and after it several million people may talk, think, and possibly dream of a combat between two cricket, football, or baseball teams.

This was forcefully brought home to me one Sunday when my stay in Chicago happened to coincide with the world series of baseball matches in New York. Chicago is rather jealous of New York, and the listeners in the former city were mostly in sympathy with the Dodgers of Brooklyn who were challenging the Yankees of New York. The excitement was intense, and for several hours each day for seven days wireless sets both at home and in public were surrounded by people alternately thrilled or depressed by the turn of the play. On the Sunday I listened in the house of a surgical friend whose excitement was clear when he held out his hands, saying "Look, they are wet with perspiration." But the baseball was not the whole of the thrill. At the same time and in the same room a television set was showing, with commentary, a football match between two famous Chicago teams. It was a trifle difficult to follow the two highly technical commentaries simultaneously but there is little which is impossible to the votaries of sport.

* * *

In this Service hospital the orthopædic staff is composed of widely different types. On the one hand we have the men who have done it all, and on the other the struggling youngster, who, through the exigencies of war, has forgone clinical experience, and now that the tumult has died down has forsaken the bayonet for the scalpel. This morning on entering the theatre I was greeted with the question: "Who's doing the list today, orthoplods or orthogods?"

Letters to the Editor

TEACHING APPOINTMENTS

SIR,—It is not easy to decide from his pseudony
letter of Nov. 22 whether "M.R.C.P." considers m
research to be a positive evil, or merely a useless
of time which might be better spent on conning textl
of general medicine or whipping up enthusiasm
flair for teaching. From my own small experien
medical research, I doubt whether it can be iden
with the "increasingly narrow specialism"
everyone engaged in the teaching of medicine
deplore. I am still more doubtful whether, as
correspondent seems to imply, there is any nece
antagonism between research experience and the a
to teach students. Naturally, these two qualitie
not always found in combination; just as the
research-workers who cannot give a clear accou
even their own work, so there are good teachers
the list type" who would be patently useless at
research. But the mere fact of having done research
not in itself make a man a bad teacher; on the cont
good students appreciate some knowledge of physi
and of recent work in medicine. Although unlike
will still be unfortunate if in response to the solicita
of "M.R.C.P." universities should decide to di
research ability from their consideration in appoi
senior staff, and so turn themselves voluntarily
training schools for medical technicians.

OUR PRESENT DIET

SIR,—I read with interest your report (Nov. 2
the Hunterian Society's debate, but it was disappoi
not to see more emphasis placed on the fact that a
figures quoted were average values and therefore req
interpretation in human terms.

The report on nutrition drawn up by the tech
commission of the Health Committee of the Leag
Nations in 1935 and 1936 points out that the v
the commission agreed are average figures and
"it is essential that they should be interpreted in
light of this fact."

Dr. Breen made a brief reference to the variatio
energy derived from a given meal; this, surely, is
crux of the whole matter, and probably accounts
the inconclusive nature of discussions on our present
nutrition. Some individuals, it seems, are able efficie
to assimilate the food they eat and our present
may be greater than their bodily requirements (case
exogenous obesity are still observed), whilst ot
whose metabolism is not so efficient, may obtain
few calories for health. This point is recognised in
terminology of the report quoted above. The t
"net calories" used in this report is defined as "
amount of energy available from the *food actu*
assimilated" (my italics).

FRACTURED CLAVICLE

SIR,—In your issue of Nov. 8 Mr. J. S. Batch
describes a somewhat elaborate invention for splint
a fractured clavicle or an acromioclavicular dislocati
May I remind your readers of the simple and effec
method which Frank Romer[1] devised for controll
the fractured clavicle by strapping?

The surgeon, standing behind the patient, raises the
on the injured side to form a right angle with the body,
draws back both shoulders firmly. This manœuvre redu
the deformity, bringing the scapula into correct position
strapping. A thin layer of cotton-wool is then placed in
axilla. A strip of adhesive strapping (about $1^1/_2$ in. w
is fixed by one of its ends over the acromion and brou
down behind the shoulder-joint, under the axilla, up anteri
to the top of the shoulder at the acromial end of the clavi
and backwards over the scapula to below its inferior an
where it ends. A similar strip is fixed starting from above

angle of the scapula. Two more overlapping strips are appl

---

[1] Romer, F. *Lancet*, 1923, i, 880.

to cover the whole of the clavicle. The arm is then lowered, and the patient is allowed to dress himself. pport is needed beyond that of an ordinary sling to take weight of the arm occasionally. The injured parts should saged daily for at least ten days. This can be done the strapping, and should be renewed at the end of four and again from time to time if slack or uncomfortable. ould be worn for at least three weeks.

ough Mr. Romer did not mention it in his paper, I mber, from the time when I was his assistant, that frst strip had a piece cut out of each side so as to ow it as it passed under the axilla and prevent chafing.

dm, S.W.1. C. V. HARRIS.

DYEING OF SURFACE ANÆSTHETICS

—In your issue of Sept. 27 (p. 493), two recent are mentioned of fatal substitution of a cocaine on for one of procaine. Fortunately this does not often; however, now and again cases are met in literature of every country. Especially the ear, nose, throat surgeon, using every day both or similar ons, often at a single operation, is always threatened this misapprehension.

The Swiss firm Ciba as long as ten years ago delivered 'Percaine' (now 'Nupercaine') solutions for surface thesia in a deep pink colour. In the Military ital at Tjimahi the same is done to all surface thetics, at my request. Our dispenser, Mr. J. de Jong, 1 minim of a 1% fuchsin solution per 50 ml. thetic, by which procedure a deep pink colour is ned. Fuchsin is a mixture of hydrochlorides of line and its derivatives. It is absolutely non-nous, does not react with the anæsthetic, and is ly soluble in water. The only disadvantage I can ine is the possibility of its staining garments when ed. However, the stains are easily removed—for nce by 5% hydrochloric acid in ethyl alcohol, or % hydrogen peroxide in 10% ammonia (verbal munication of J. de Jong). The advantage is that an illiterate can be taught that tinted solutions are ted for injection. Also when the drugs are out of labelled bottles and in containers on a tray the colour always indicate a surface anæsthetic, which is very ring indeed to the surgeon. The colour is readily le even in a semi-dark room.

my opinion it would be advisable to prohibit use dyed surface anæsthetics.

ary Hospital, Tjimahi, Java. O. L. E. DE RAADT.

TUBERCULOSIS IN EUROPE

—The leading article in your issue of Nov. 22 cerned with a recent report of the International mittee of the Red Cross on health conditions in a ber of European countries, including Germany.

You point out that tuberculosis mortality figures in many today require very careful scrutiny, and you rightly sceptical of the committee's statement that the American zone (including the Berlin sector) the rculosis death-rate "rose from 20 per 10,000 inhabi-s in April, 1946, to 37·5 in April, 1947" (as against in 1933). In a report of the military governor, U.S. , on public health and medical affairs, the death-from tuberculosis in the U.S. zone is given as 6·7 per in April, 1946, and 6·6 in March, 1947. Hence the tality-rates given by the Red Cross committee are 3–5 times the official figures; and whereas the mittee's figures indicate an alarming doubling of rates in a year, according to official data no change taken place.

This is not an isolated instance of carelessness. Thus committee states that in Schleswig-Holstein (British) the tuberculosis death-rate, "which was 6·3 per 00 inhabitants in 1934/1936, rose to 22·1 for the half of 1946." Actually (official British sources) the rculosis death-rate for this Land in the first half 1946 was 6·6 per 10,000 (the *notification*-rate of *new* was about 22); again the committee presents a e three times the correct one, and a startling rise n there was none. Some of the committee's com-ons are no less careless, to say the least. In almost country discussed, an increase in the number of rculosis cases on the registers is taken as signifying an increased incidence of the disease; but in Spain this increase "does not arise from the spread of the disease by contagion, but from the fact that the methods for the detection of tuberculosis are more rapid." In similar tendentious vein, the report states that there are "over 12,000 beds for consumptives in Spain in sanatoriums supplied with all technical means for modern surgical treatment": whereas the 23,000 beds for tuberculosis in August, 1946, in the British zone, with a similar population and a lower tuberculosis mortality, are described as "only 23,000 beds . . . which were not sufficient to admit all infectious cases to hospital."

It is a pity that the names of the members of the medical division of the International Committee of the Red Cross, who are responsible for this uncritical and superficial review, are not given.

London, N.W.3. P. D'ARCY HART.

*** Our leading article quoted the committee as saying that the tuberculosis situation is "particularly disastrous" in Germany, Austria, and Rumania. Actually the committee applied these words to the general situation in these countries.—ED. L.

ROWLEY BRISTOW MEMORIAL

SIR,—Many friends of the late Walter Rowley Bristow have expressed a wish to share in a memorial to him. It has been suggested that his life and work would be best commemorated by the foundation of an annual or biennial memorial lecture, to be delivered, if circumstances permit, alternately in Great Britain and in the United States, the two countries in which he was acclaimed as an outstanding leader in orthopædic surgery, and where he was held in such warm regard. When a sufficient endowment fund has been accumulated it will be entrusted to the British Orthopædic Association. Contributions to this fund are now invited, and can be sent to George Perkins, 149, Harley Street, London, W.1.

G. R. GIRDLESTONE GEORGE PERKINS
CHARLES MAX PAGE HARRY PLATT.

"CHORIONIC GONADOTROPHIN"

SIR,—To question the propriety of any accepted phrase in science may at first appear priggish and pedantic. Accuracy and ease of thought, however, depend largely on exact language; and I offer no other excuse for the following note.

The term "chorionic gonadotrophin," whose suitability is now questioned, was adopted in the past because of a hypothesis which later work has not confirmed.

The word "chorion" is derived from the Greek χόριον, which like the Latin *corium* means "leather," and strictly indicates therefore the subepithelial tissues; but in our language it denotes the outermost membrane of the fœtus. The adjective "chorionic" is commonly applied to the gonadotrophin which is produced by the placenta of a pregnant woman and is present in high concentration in her blood and urine; so used the term "chorionic gonadotrophin" implies to many that the hormone is produced by the chorion of the fœtus. Known facts do not support such a belief. The fœtus has no need for abundant supplies of this hormone, and little if any can be detected in its blood or other parts of its body. These considerations alone make it probable that the gonadotrophin required by the mother is manufactured by her tissues and not by those of the fœtus. Furthermore, in some animals, including the mare, the fœtal and maternal components of the placenta can be separated by manipulation and so analysed apart; and in the mare it has been found in this way that gonadotrophin is present in large amount in the maternal but not in the fœtal component.[1] It is therefore concluded that in the mare placental gonadotrophin is elaborated without a doubt by maternal tissues and not by the chorion of the fœtus. Although the precise origin of placental gonadotrophin has not been determined in every mammal, the process is a fundamental one and is likely to be the same in all.

As a mere argument it may perhaps be suggested that the hormone arises in the subepithelial structures—i.e., the corium (or chorion) of the uterus—and that on this

---

1. Catchpole, H. R., Lyons, W. R. *Amer. J. Anat.* 1934, 55, 167.

account the term "chorionic gonadotrophin" may after all be correct. But this is a mere debating point, for the word "chorion" in general medical parlance indicates the external fœtal membrane and not the corium of the uterus.

I suggest that, to prevent confusion of thought, "placental gonadotrophin" might well replace the more questionable term "chorionic gonadotrophin" at present in use.

Marlborough, Wilts. HAROLD BURROWS.

SUBSTITUTE FOR CANADA BALSAM

SIR,—'Siloxane' or 'Silicone,' a synthetic resin with a chain of silicon and oxygen alternately, promises to be a useful substitute for Canada balsam, in thick mounts, as it is practically water-white. Its refractive index is much the same as that of Canada balsam, and the technique for mounting is similar.

Mental Hospital, Wells, Somerset. D. S. SPENCE.

AMBULANCES

SIR,—Your leading article last week asks for information concerning the experience of doctors calling ambulances for their patients. As the Emergency Bed Service calls some 10,000 ambulances a year our experience may be of interest to you.

This service, as you know, deals only with patients who require immediate admission to hospital—immediate being deemed to mean within a day. A certain number of them are cases of desperate urgency, in which case the general practitioner authorises us to call for a "life and death ambulance," which, I understand, comes from the accident service and invariably leaves at once. In the remainder of the cases the patients are seriously ill and in need of treatment, but a short delay is probably of no serious consequence.

Whenever an ambulance is called the ambulance service is asked when the vehicle will leave, and the amount of delay indicated by this reply is the figure used in the following table. The cases tabulated have been selected at random, being the first 100 ambulances called in the months indicated.

SUMMARY OF DELAYS REPORTED ON 100 AMBULANCE CALLS MADE AT THE END OF EACH QUARTER TO THE LONDON COUNTY COUNCIL AMBULANCE SERVICE AND OTHER AMBULANCE SERVICES IN GREATER LONDON

Delay	December, 1946		March, 1947		June, 1947		September, 1947	
	L.C.C.	Others	L.C.C.	Others	L.C.C.	Others	L.C.C.	Others
None ..	37	66	44	68	65	73	59	83
15 min.	—	3	4	6	2	6	4	5
20 ,,	2	4	4	3	4	6	3	3
30 ,,	9	18	8	10	4	6	7	6
45 ,,	12	1	4	2	5	2	7	1
1 hour	28	6	17	10	18	7	13	2
2 hours	9	1	9	1	2	—	5	—
Over 2 hours	3	1	10	—	—	—	2	—
Total ..	100	100	100	100	100	100	100	100

It should be emphasised that where a doctor states that the case is desperately urgent an accident ambulance can be called, but some of the long delays shown must represent a great deal of anxiety to patients and doctors.

The ambulance services are at present suffering acutely from an inability to replace their ambulances, most of which are pre-war vehicles, and it is strongly to be hoped that the advent of the National Health Service will enable them to obtain high priority for replacements.

R. E. PEERS
Secretary, Emergency Bed Service.

10, Old Jewry, London, E.C.2.

Parliament

FROM THE PRESS GALLERY

National Assistance Bill

IN moving the second reading of this Bill[1] in House of Commons on Nov. 24 Mr. A. BEVAN, Min of Health, described it as the coping stone on the struc of our social services because it provided for the 400 people on outdoor relief, the 100,000 in institut and the 30,000 deprived children who still rema under the poor-law. Assistance, he continued, wa future to be a national responsibility and welfa local responsibility. Therefore the National Assist Board—as it was to be renamed—would pro financial help on a scale to be determined by regula presented to Parliament by the Minister of Nati Insurance.

Turning to the people who would need special l Mr. Bevan said the board would have the dut providing maintenance of the blind while the authorities would be responsible for schemes for training and welfare. The welfare authorities would have a special responsibility for the tuberculous. system of mass radiography, and the encouragemen people in the early stages of the disease to give up work and undergo treatment, would be continued extended. The provision under which tubercu allowances ceased when it was found that the pa was incurable would be abolished. The treatmen pulmonary tuberculosis would be the responsibilit the National Assistance Board on the one side and regional hospital boards on the other.

The proper care and welfare of the aged, Mr. Be declared, was the peculiar problem of modern soci As people grew older they became jealous of t independence and the Government had therefore dec that the workhouse must go. Instead the wel authorities would be given power to establish spe homes where our old people would enjoy the maxin of privacy and independence. "Bigness," Mr. Be said, "is the enemy of humanity," and the optin limit for these homes must be about 25 to 30 reside who should belong to mixed income groups. The cha ter of the homes would be destroyed if merely the n indigent lived in them. Obviously it would not possible for these hotels to spring up overnight would take some time to build and equip them. "H ever," concluded Mr. Bevan, "we have set our feet u that road, and we intend to march upon it as qui as possible."

Mr. WALTER ELLIOT was glad that the tubercul schemes were being maintained and extended. would, he pointed out, place on the Government a greater responsibility for finding the nursing staff make sure that treatment was available. At present could not staff all the existing beds, and as long we were in that position it was not necessary, or e advisable, to talk about using more money for bri and mortar provisions. Mr. Elliot was a little une about some of the powers taken by the Bill. For insta any aged or infirm person could be removed from house on the certificate of one medical officer of hea supported by the court. Usually at least two certifica were necessary before a citizen could be removed fr his house and detained under an indeterminate sente or order.

Mr. SOMERVILLE HASTINGS looked upon the Bill one of the best that had been introduced in the pres Parliament. He was grateful that in future the cost hospital treatment would not be counted as means, that pensioners would be allowed some pocket mo while they were in hospital. He hoped that the r homes would be situated as near as possible to wh the old people had spent their lives. Dr. BARNET STR also welcomed the new provisions in regard to tub culosis allowances. Doctors had had imposed up them the duty of offering the death sentence to th and women. Now that they had a remedy it would make life much easier.

---

[1] See *Lancet*, Nov. 8, p. 692.

Medical Practitioners and Pharmacists Bill

In the House of Lords on Nov. 27 this Bill was read a third time and sent to the Commons.

Punishment and Reform

The Criminal Justice Bill, said Mr. CHUTER EDE, in moving its second reading on Nov. 27, was not intended to weaken the effectiveness of the law, but to rationalise make more flexible methods already available for dealing with convicted offenders. After describing the main provisions of the Bill, already set out in our columns,[2] Mr. Ede turned to the question of abolishing the death penalty. the war, he pointed out, there had been an increasing tendency for criminals to carry lethal weapons. At the time when they had to deal with a phenomenal increase in cases of violent crime, and with the emergence of the armed criminal, our police forces were below establishment. The Government therefore could not regard the time as opportune to include in this Bill a provision for suspension or abolition of the death penalty. But it recognised that this was a matter on which strong individual conscientious feelings were held, and that the division did not follow the usual party lines. If an amendment to deal with the death penalty was moved at the report stage of this Bill the Government would leave the final decision to a free vote of the House.

Viscountess DAVIDSON declared that the powers given to the courts to secure mental treatment for juvenile offenders on probation would only be effective if there were people capable of carrying out the treatments indicated in clause 4 of the Bill. Some idea of the personnel which would be required could be gathered from the following figures for all indictable juvenile offences in 6: under 14 years, males 22,922, females 1500; to 17 years, males 17,349, females 1732; 17 to 21 years, males 15,118, females 2324. There were at present some medical men and women capable of carrying out this work in the bigger centres, mainly in London, but their numbers barely covered the opportunities for work of this kind at present in existence. All clinics were overworked today, and no provision was made in the Bill, so far as she could make out, for adding to the numbers of trained medical or lay personnel. There were bodies who were quite capable of carrying out suitable training if grants could be made to them. It would probably be said that such provision came within the scope of the National Health Services Act rather than the Criminal Justice Bill. But there was no power given in the latter measure to the judiciary to require the Minister of Health to provide for the training and appointment of officers for this purpose. So far as she could gather the maximum number of people who were ready and trained to deal with juvenile offenders was about 50.

Dr. SANTO JEGER averred he was not one who liked to cry stinking fish about his own profession, but he regarded the medical attention in prisons as inadequate. It was often perfunctory, although he agreed that many prison medical officers were skilful, took their duties seriously, and gave their charges good medical care. He thought every medical officer in a prison should be compelled to take a diploma in psychological medicine and to attend refresher courses from time to time. Though a non-smoker himself he urged that prisoners should be allowed to smoke and such punishments as solitary confinement, flogging inside prisons, and the imposition of bread and water diet, should be abolished. He was emphatically opposed to the retention of flogging as the use of flogging was associated with a basis of sexual perversion, not necessarily deliberate and conscious. Its abolition he believed would lessen the brutal atmosphere which existed in so many of our prisons.

Mr. STROSS held the provisions relating to young offenders to be the most important part of the Bill. If we wanted to keep down the number of habitual criminals we must ensure that young offenders were treated in such a way that they never again appeared before the courts.

QUESTION TIME

Pensions for Psychotics

Replying to a question Mr. G. BUCHANAN, Minister of Pensions, stated that the statutory tribunals had determined 2100 appeals by men and women discharged from the Services against the rejection of pension under the broad heading of psychosis. Of these the tribunals have allowed 450.

Royal Commission on Population

Major E. A. H. LEGGE-BOURKE asked the Minister of Health when the report of this commission might be expected.—Mr. BEVAN replied: I am informed by the commission that owing to the delays in the tabulation of the family census, the report will not be ready until next year.

Medicine and the Law

Medical Report without Patient's Knowledge

Dr. R., chief medical officer to an Irish insurance company, was adjudged "guilty of infamous conduct in a professional respect" at a hearing in Ireland last month[1] for having asked a medical practitioner to furnish "confidentially" a medical report on one of his patients.

It appeared that the patient was an elderly woman whose daughter wished to take out a policy to cover the prospective expenses of her mother's funeral. The daughter gave the insurance agent the name of Dr. K., her mother's medical attendant. In due course Dr. R., acting for the company, applied to Dr. K. for a report on the mother's medical history. Dr. K. in answer refused the application and described it as "irregular and unethical." Dr. R. rejoined that his request was for the purpose of assisting the poorer classes to effect insurance on a member of the family so as to protect themselves against funeral expenses; he added that Dr. K.'s refusal was "antisocial." This exchange of epithets was ended by Dr. K. asking for the letter back so that the correspondence could be referred to the Medical Registration Council of Ireland for decision. Several months later he received a second application from Dr. R. of the same nature and apparently relating to the same patient. He then sent the letter to the council.

The charge formulated against Dr. R. was that he had asked Dr. K. to furnish, for reward, a private report respecting the past and present state of health of a patient without the knowledge or consent of the patient. Dr. R. in his evidence stated that he had been chief medical officer to the insurance company since 1932 and that it was the company's practice in such cases, at the request of the person who proposed to take out the policy, to ask the medical attendant of the insured to make a report. He stated that 98% of the doctors who were asked supplied these confidential reports. Questioned as to what happened if doctors refused, he said that "accasionally, very occasionally" doctors did not reply, and on his sending a reminder they answered that they regretted they could not accede to his request. That ended the matter. Asked how it happened that he had sent a second request to Dr. K., he answered that, when he sent the second letter, he would not have seen the first proposal; there might have been two different proposals from children of the patient living in different places.

In announcing the decision of the tribunal, the chairman said that the council took a very serious view of any action which might impair the patient's trust in the confidential nature of any information obtained by a medical attendant about his patient. The council considered that information should not be disclosed without the patient's knowledge or consent. The action of Dr. R. was endangering this confidence. The council, however, decided to postpone judgment until their meeting in two years' time. Before that date Dr. R. would be required to send to the registrar, for the use of the council, the names of professional and other men of standing who might be willing on application to testify to their knowledge of his professional behaviour in the interval.

Obituary

JOHN FRASER

BT., K.C.V.O., M.C., M.D., CH.M. EDIN., LL.D., F.R.C.S.E.

WE have to record the death of Sir John Fraser, principal of the University of Edinburgh since 1944, and previously regius professor of clinical surgery. Both in surgery and in affairs he was a man of high ability, with a fresh and vigorous mind directed towards the future.

Press Portrait Bureau

He was born in 1885 at the small town of Tain in Ross-shire, the son of James Fraser and Margaret Mackay. From school days at Tain Academy he went to Edinburgh and graduated in medicine with honours in 1907. Thereafter he was resident surgeon successively at the Royal Infirmary, the Sick Children's Hospital, and the Chalmers Hospital, till 1910 when he took his F.R.C.S.E. and CH.M. He also studied in Paris and Freiburg. His first honorary post was at the Sick Children's Hospital, to whose honorary staff he was elected in 1912; and at that time he did much work, both clinical and experimental, on tuberculosis of bones, extending his researches to the differentiation of human and bovine tubercle bacilli. In 1914 he produced his book on *Tuberculosis of the Bones and Joints in Children*, which was dedicated to his chief, Harold Stiles, and was well received both by colleagues and students. Further inquiry on these lines was interrupted by the war, and from 1914 to 1918 he served with the R.A.M.C., winning the Military Cross and a mention in despatches: in observations on traumatic shock he collaborated among others with Cuthbert Wallace, with whom he afterwards wrote *Surgery at a Casualty Clearing Station*. On returning to Edinburgh he was elected assistant surgeon to the Royal Infirmary, and his surgical interests widened further.

A fluent and resourceful lecturer, Fraser took pains to understand his audience so that they should understand him. The Edinburgh undergraduates of 1925 welcomed his appointment to the regius chair because he paid them the compliment of taking them seriously—addressing them indeed as equals who were entitled to be critics. They welcomed him too as a young man who had lately travelled their own road (with much distinction) and who had no use for the idea that the highest peak of Edinburgh's glory was touched in the days of Lister and Syme. Nor were they disappointed: the new professor had brilliance both as surgeon and teacher, and was true to the ideal of scientific practice imparted by Stiles his predecessor.

During his active years as a surgeon Fraser's fame spread widely. His book *The Surgery of Childhood*, which came out in 1926, was the first of its kind and a competent work. He lectured in Sydney and was made F.R.A.C.S.; he became an honorary fellow of the American College of Surgeons and of the American Surgical Society; his private practice grew; and his appointment as surgeon to the King in Scotland brought him a knighthood in the Royal Victorian Order in 1937. During the late war he was consulting surgeon to the Military Hospital, Edinburgh, and to the Royal Navy in Scotland, and in 1943 he was created a baronet. Throughout these years, however, his professional work was increasingly mingled with the affairs of the university and the nation. In a portrait sketch at the time of his appointment the university magazine, the *Student*, said:

"While talking to Professor Fraser, one receives the impression that his greatest triumphs are yet to come at the conference table. For he has the subtlety of Odysseus, grasps your argument beforehand, penetrates the thou which lie behind it, and gives you his answer in a cl confection of compliments. There is a strange disp between the essential novelty of his thought and the sembl of orthodoxy which he throws over it. He loves to act lion in the guise of the lamb, and this is the very quintess of diplomacy."

He was a member of the Royal Commission on Licen of 1930–31, of the consultative committee of the A Medical Services, and of the scientific advisory commi of the Department of Health for Scotland. N concerned about the conditions of student life, he he to form the plans of his friend Sir Donald Pollock, in 1943 gave about £250,000 in trust to stimulate develop student activities. In 1944 he succeeded Thomas Holland as principal.

The three years spent in this new work characterised by intense devotion: no effort was sp to master the details of university problems great small. Almost from the first, however, he was ha capped by ill health, leading to grave illness last y and he was handicapped also, in a sense, by a High reserve and a shyness which in daily contacts made courteous manner rather formal. Nevertheless in a t of great difficulty following the war he achieved n for which Edinburgh will long be grateful.

Sir John Fraser married Agnes Herald, of D and they had a daughter and a son who succeeds to baronetcy.

ALEXANDER MacCORMICK

K.C.M.G., M.D. EDIN., HON. F.R.C.S.

THE influence of Sir Alexander MacCormick on development of surgery in this continent, writes Australian correspondent, has been profound. practical surgeon, by his judgment, skill, and anatom approach to surgery, he taught by precept and exam many thousands who were associated with him assistants, house-surgeons, and students.

Sydney Morning H

Born in 1856 at Taynish, in Argyllshire, MacCorm received his early medical education at the Univer of Edinburgh, where he was a class-mate of Sir Arthur Conan Doyle, David Orme Massey, and his life-long friend Dr. Robert Scot Skirving. After graduating M.B. in 1880, he became a demonstrator in physiology at Edinburgh and later house-surgeon at the Liverpool Royal Infirmary to E. R. Bickersteth, who had a great influence on his work. In 1883 he came to Australia under the ægis of his friend Anderson Stuart, as the first demonstrator in anatomy to the new medical school of the University of Sydney. To this period of anatomical research belongs his thesis on the musculature of the limbs of the Australian native cat, for which was awarded the Edinburgh M.D. with gold medal 1885.

In the same year he was appointed assistant surge to the Royal Prince Alfred Hospital, Sydney, wh he was one of the first to introduce antiseptic metho and the teachings of Lister. Here he laid the foundatio of his great surgical reputation. Appointed to the sen staff in 1889, he worked actively at the hospital un he reached the retiring age in 1915; then he joined t staff of the St. Vincent's Hospital where he remained active member of the staff until 1932. He was also member of the staff of the Sydney Hospital and of t Prince Henry Hospital.

Although MacCormick was lecturer in surgery in t University of Sydney for over a quarter of a centu he was not considered a good clinical teacher. But t two tributes which follow show that for some of l pupils at least this was not true. "He spent little tid in bedside instruction," writes B. T. E., "but to the who followed him closely there was a great deal to lea he was always ready to answer questions. In the theatre there were large audiences of students visiting practitioners. His skill and speed in the ormance of intricate surgical dissections was unique d he became a master of almost every branch of surgery. ny, like myself, have established their practice n his teaching and example."

J. S. takes up the tale: "It would be impossible to agine anybody leading a more strenuous and useful than MacCormick. His mental and physical stability enormous, enabling him to outlast many a younger . To his patients and to their tissues he was gentle kind. His field of activity was the whole body, and had an uncanny judgment and a superb dexterity. excellent teacher of those who worked with him. he ght by example. Generous and charitable, he never wed his right hand to know what his left was doing."

MacCormick was made an honorary fellow of the yal College of Surgeons of England in 1900 and of the al College of Surgeons of Edinburgh in 1905, and he a foundation fellow of the Royal Australasian College f Surgeons. He was knighted in 1913 and appointed K.M.G. in 1926. With Dr. Scot Skirving, he had served consulting surgeon in the South African War with the w South Wales contingent, when he was mentioned despatches. He also served from 1914 to 1917 in Middle East and in France.

The volumes of the *Australasian Medical Gazette* m 1884 to 1906 bear testimony to his skill and ability, d in all he published more than 30 articles.

One of his best-known cases was that of a man who in had a V-shaped excision performed for a cancer of the . A year later, a considerable part of the lower jaw was moved for a recurrence, with a large part of the cheek and submaxillary gland. Three and a half months later, ramus of the jaw, part of the parotid, the pillars of the ces, and the tonsil were removed. Four months later a ther recurrence was treated. In 1892, the patient was and was shown at a meeting of the Intercolonial Medical gress in Sydney. Through the opening in the side-wall the pharynx, it was possible to follow the movements of the glottis during swallowing. These movements were studied Anderson Stuart, who, with MacCormick, described in the *Journal of Anatomy and Physiology* in 1892.

MacCormick's attention to the patency of the whole ry tract before closing the abdomen in gall-bladder ery was meticulous and was one of his most practical hings. He was at his best in intricate dissections lving the tongue, maxillæ, and glands of the neck. operation he described in 1899 for removal of cancer the tongue was well ahead of his time, while his ation for irreducible dislocation of the metacarpal t of the thumb, by passing a tenotome through the of the joint and cutting the thick anterior ligament nst the phalanx, still remains the simplest and best hod of meeting this difficult problem.

n 1926 he presented his private hospital, The Terraces, ether with £25,000 and lands for its extension, to the esbyterian Church of New South Wales, and it is now nown as The Scottish Hospital. He was a member of the Royal Yacht Squadron and commodore of the Royal ydney Yacht Squadron; when about seventy, he iled his yacht *Ada* from England to Australia through Panama Canal. On his retirement, he went to live t St. Brelade, Jersey, and he escaped internment by few hours when the Channel Islands were invaded in 1940. After the war he returned, and it was there he ed on Oct. 25.

ELIZABETH COWPER EAVES

M.D., B.SC. LOND., D.P.M.

Dr. Elizabeth Eaves, lecturer in physiology in the University of Sheffield and consulting neuropathologist to the South Yorkshire Mental Hospital, died on Nov. 21 after a short illness.

Holding her B.SC. she was appointed demonstrator in physiology at the University of Sheffield in 1909, and she continued to work in this department until her death, serving under four professors. In her chosen specialty of neurohistology she devised staining methods for nervous-system tissues. Colour-vision was another of her interests, and she had lately completed a paper presenting the results of years of detailed observations. From this work Dr. Eaves turned to medicine, taking her M.B. in 1922, the D.P.M. two years later, and her M.D. in 1925.

As president of the local association of the Medical Women's Federation Dr. Eaves for many years spared no effort to obtain equality for women students, especially on the question of resident student posts, and she undertook a follow-up of all the women students from Sheffield who had qualified in the last 30 years, to justify the existence of the woman medical student. She was also at one time corresponding secretary of the Medical Women's International Association.

During the world war she spent her university vacations doing locum appointments, mainly in hospitals for nervous diseases. Those who visited Dr. Eaves at her home discovered with appreciation her gifts as a pianist.

Public Health

Foul Rivers

ON the second reading of the River Boards Bill the Duke of Devonshire quoted Greek, somewhat to the confusion of *Hansard*. He was recalling what Herodotus recorded of the exemplary habits of the ancient Persians. One need not flinch from offering an English translation of the passage: "Because of their special reverence for rivers they neither urinate nor spit into a river nor wash their hands in it, not do they allow anyone else to do so."

Such respect for cleanliness, health, and amenities puts us to shame some 24 centuries later in an age when the water-borne sewage of cities and the poison of industrial effluents are allowed to contaminate our streams and estuaries. Even the new Bill, as its sponsors have to admit, does nothing in itself to check this appalling pollution. Its scope is invincibly modest. It is a typical "departmental" Bill, devoted to the mechanics of administration.

The Central Advisory Water Committee, of which Lord Milne has been chairman, have looked round England and discovered that there are 45 fishery boards, 53 catchment boards under the Land Drainage Act, and, in all, some 1600 bodies responsible for dealing with river pollution. The Milne Committee proposed to substitute 29 larger and more powerful authorities. The new Bill is not even so definite as that. New "river board areas" are to be mapped out presently by departmental order. It is not thought worth while to disturb the Port of London Authority's powers over navigation and pollution, the London County Council's powers of preventing flooding, or the supervisory jurisdiction of the Thames Conservancy. Consequently the Thames, Lee, and London areas are excluded from the Bill but may be brought in later by another set of departmental orders. The main purpose of the new Bill is to set up the projected river boards and to transfer to them the functions, powers, assets, and liabilities of the existing bodies. On any fresh provisions for enforcing the law, or for conserving water so that we do not witness the irrational sequence of floods and droughts, the Bill appears to be silent. But it was officially stated during the House of Lords debate that the Milne Committee has, at the Government's request, set up a subcommittee to examine what fresh legislation is required for coping with pollution. Thus, even in a period of streamlined law-making, we progress but slowly towards ending the scandal of our fouled rivers.

Shortly before the debate a school of porpoises was observed off Westminster. But the riparian residents of Chelsea and Chiswick cannot watch from their windows the leap of the salmon. Mature fish cannot survive the pollution of the Thames below London Bridge. Apart from the amenity of clean water, we lose a by no means negligible source of food-supply. In former centuries, it is sometimes said, such was the plenty that wages agreements used to stipulate that the agricultural labourer should not be obliged to accept salmon in lieu of money more than twice a week. Mentioned in the recent debate, and apparently accepted by the Master of Trinity in his *English Social History*, the story is heavily challenged by a contributor to *Notes and Queries* in the issue of Nov. 15. Whether it be true or false, the

In May, 1946, the institute moved into new quarters in London Street, and this made it possible to extend both clinical and educational work. There were 1071 attendances at the psychopathic clinic, and 160 new cases came for treatment—about the same number as in 1938. But the demand for the clinic's services outruns its capacity, and it is estimated that at least five times as many cases would be dealt with if money was available to pay for medical and other technical staff. Even a small additional whole-time or part-time paid technical staff, it is thought, would make this possible, and to ensure that better use was made of valuable data collected in the records.

The conditions covered include mental defect, low intelligence, psychosis and borderline psychosis, psychoneurosis. Character disorders, organic disorders, and alcoholism. Patients are referred to the institute by courts, doctors, clinics, philanthropic societies, relatives and friends, and social workers; and some patients come of their own accord. Medical, psychological, and social treatment is undertaken, and every patient is thoroughly examined physically and mentally; his intelligence is tested and his social history is studied by a psychiatric social worker. The results are surveyed and discussed by one of the medical directors, and a comprehensive report of the findings, with recommendations, sent to the court or other body which referred the patient to the clinic. Dr. Denis Carroll, Dr. Frederick Dillon, Dr. Edward Glover, Dr. T. Rowland Hill, Dr. Emanuel Miller, and Dr. J. D. W. Pearce are the directors of the clinic, and there are in addition 19 other doctors on the medical staff. More subscribers are needed to help this careful and useful piece of voluntary work.

RADIOACTIVE TESTOSTERONE

WITH the aid of the radioactive isotope of carbon, C^{14}, radioactive testosterone, the first example of a synthetic radioactive sex hormone, has been produced in the department of chemistry at Harvard University.[1] It is expected that this will lead to advances in the knowledge of the interrelations of steroid hormones and cancer.

MEDICAL SUPPLIES

FROM Dec. 1 the Ministry of Health will take over from the Ministry of Supply responsibility for purchasing medical supplies for the Government. This transfer is in conformity with the general policy of handing over various war-time functions of the Ministry of Supply to the appropriate Government departments. The functions transferred include the purchase and inspection of Government requirements of drugs, dressings, and medical and surgical equipment, together with responsibility for sponsorship of firms producing these supplies for civil needs. For the present, the regional controllers of the Ministry of Supply will continue, on behalf of the Ministry of Health, to deal with matters normally considered at the regional level. All correspondence formerly addressed to the Directorate of Medical Supplies (including Penicillin Production Control), should from Dec. 1 be sent to the Secretary, Ministry of Health, Whitehall, S.W.1. The telephone number (Abbey 7788) remains unchanged, but the new telegraphic address will be " Localise, Parl, London."

SICK-BAY FOR CIVIL SERVANTS

A SICK-BAY was this week opened at Moray Lodge, Campden Hill, for civil servants of the lower-paid groups appointed to posts in the London area and living in hostels or lodgings. The sick-bay will be administered by the Ministry of Health, and the British Red Cross Society will be responsible for its day-to-day management. The Treasury Medical Adviser and his staff will act as medical officers, but private doctors will, of course, be free to visit their patients in the sick-bay. Cases of serious or notifiable infectious disease will not be accepted, and the sick-bay will deal only with the home-nursing type of case.

University of Oxford

On Nov. 22 the degree of D.M. was conferred on D. M. T. Gairdner (in absentia), and the degree of B.M. on D. M. L. Moran.

Royal Society of Medicine

The William Gibson research scholarship has been awarded to Dr. Alice Palmer, of Sydney, for her proposed research on the circulation in pregnancy.

Royal College of Physicians

The by-laws have been amended to give members more voice in the affairs of the college. In future at least two general meetings of members must be held each year, and a standing committee has been set up to concern itself with their interests. At the first statutory meeting, held on Nov. 27, with Lord Moran, the president, in the chair, 133 members were present. The following were appointed to serve on the standing committee: Lord Moran (ex-officio), Dr. W. R. S. Doll (chairman), Dr. M. J. McArdle (secretary), Dr. H. S. Morley, Dr. E. Halliwell, Dr. J. Holmes, Dr. J. F. Bromley, Dr. P. L. Mollison, Dr. W. J. O'Donovan, Dr. J. H. Hunt, Dr. E. Bywaters, Dr. C. Wilson, Dr. G. E. F. Sutton, Dr. A. Leishman, Dr. E. Darmady, Dr. K. A. Latter, Dr. R. Johnstone, Dr. R. Cove-Smith, Dr. J. R. Forbes, Dr. Helen Dimsdale, Dr. W. E. Gibb; and Dr. J. F. Loutit and Dr. L. W. Batten, who were also elected representatives on the council of the College.

London Hospital

Dr. A. G. Leatham has been appointed Sherbrook research fellow to the cardiac department of the hospital.

Pharmaceutical Society of Great Britain

On Thursday, Dec. 11, at 7.30 P.M., at 17, Bloomsbury Square, London, W.C.1, Mr. Adrien Albert, PH.D., will speak on protein structure and its pharmaceutical significance.

Medical Defence Union

Dr. P. H. Addison has been appointed assistant secretary to the union. Dr. Addison, who qualified in 1933, has served with the I.M.S. for ten years.

Gordon Hospital, London

On Dec. 2, the Duchess of Kent formally opened this hospital. The hospital which was first started in 1884, completed its rebuilding scheme in 1939, but during the late war it was requisitioned as a hostel for troops and its equipment transferred to the Victoria Hospital, East Grinstead.

Bearsted Memorial Hospital

The new unit of this hospital at Lordship Road, Stoke Newington, N.16, is now open for the reception of patients irrespective of religion or creed, and the board ask that emergency cases and abnormalities should be referred to the hospital for admission and antenatal treatment.

N.A.P.T. Colonial Scholarships

The National Association for the Prevention of Tuberculosis have awarded scholarships to the following for training in Great Britain in 1948:

Dr. Motala, in charge of Kibongoto Tuberculosis Hospital, Moshi, Tanganyika; Dr. V. E. Donawa, grade A medical officer (tuberculosis), medical department, Trinidad; Dr. M. H. Sherif, medical inspector in Sudan Government.

International Association for Prevention of Blindness

An honorarium of $1000 to promote research work on ophthalmology is offered through the American members of the staff of this association.

The award will be made in connexion with the 16th Concilium Ophthalmologicum, and the jury will consist of the officers and executive committee of the association. Papers may be presented by any responsible research-worker. The subject is to be Simple Non-inflammatory Glaucoma and may include anything definitely relative to the question. The matter must be new and of such value, in the judgment of the jury, as to merit this recognition. Papers may be written in English or French; they should be either unpublished or else published between the present date and Oct. 15, 1949; and they should reach the secretary of the association, 66, Boulevard St. Michel, Paris, not later than Oct. 15, 1949.

Scottish Defence Union's Report

During the year 1946–47 the membership of the Medical and Dental Defence Union of Scotland increased from 5742 to 5905. The annual report gives the assets as £34,882, representing a reserve of £5 18*s*. 1*d*. per member. During the past year the main grounds in respect of which claims arose were: error in prescription; amputation of the wrong finger; omission to remove tourniquets after operation; failure to X ray fracture; X-ray, diathermy, and radiant-heat burns; failure in swab check after operation; wrongful certification of insanity; negligence in diagnosis; negligence after unsuccessful dental extraction; and libellous remarks to relative of patient.

---

[1] Turner, R. B. *Science*, 1947, 106, 248.

Pan-American Congress of Ophthalmology

Among the guests who are to address the third Pan-American Congress of Ophthalmology, which is to be held in Havana from Jan. 4 to 10, are Sir Stewart Duke-Elder whose subject will be Penicillin in Ophthalmology, and Dr. Elizabeth Cass (Gibraltar) who will speak on Strabismus.

Deferred Call-up of Laboratory Trainees

Under an arrangement announced by the Ministry of Health, trainee laboratory technicians may apply for deferment of call-up until their training has been completed. Deferment is to be granted subject to provisos as to age, suitability of the training provided, and satisfactory progress in training.

Royal Society of Arts

On Monday, Jan. 26, Dr. C. H. Andrewes, F.R.S., will speak on Progress in the Fight against the Common Cold, on Feb. 2, Prof. A. C. Frazer on the Metabolism of Fats, and on Feb. 9, Sir Jack Drummond, F.R.S., on Fats in the Life of the Nation. All these Cantor lectures will be given at the house of the society, John Adam Street, Adelphi, London, W.C.2, at 4.30 P.M.

Middlesex Hospital Arts Society

This society is holding their annual exhibition in the boardroom of the hospital, London, W.1, on Dec. 15-18, from 11 A.M. to 6 P.M. (4 P.M. on the 17th). One of the main sections will be work by members of the Photographic Society, and Prof. J. McIntosh and Dr. K. B. Merling will show electron photo-micrographs, and Mr. W. H. S. Cheavin, F.R.M.S., philatelic research by X rays.

Chairmanship of Food Investigation Board

Sir Frank Engledow, F.R.S., Draper's professor of agriculture in the University of Cambridge, has been appointed chairman of the board in succession to the late Sir Joseph Barcroft, F.R.S. The board, which has research stations at Cambridge, Aberdeen, and East Malling, Kent, is concerned with the conduct of research into the properties and behaviour of foodstuffs, and the scientific problems involved in their storage and transport.

Ling Physical Education Association

A conference on remedial gymnastics will be held at Sloane School, Hortensia Road, Chelsea, S.W.10, from Monday, Dec. 29, to Friday, Jan. 2. The aim of the conference is to emphasise the importance of the prevention and cure of minor defects in school-children; to stimulate interest in the specialised treatment of those more seriously handicapped; and to give a picture of medical gymnastics as carried out in this country. The medical speakers will include Dr. Harold Balme (Place of the Remedial Gymnast in the National Health Scheme), Dr. Doris Baker (Postural Foot Defects), Prof. A. B. Appleton (Feet and Posture), Dr. F. S. Cooksey (Postural Defects of the Spine), Miss M. Forrester-Brown (Team Work in the Prevention and Cure of Postural Defects), Dr. J. L. Dunlop (Place of the Educational Gymnast in a School Health Service). Further information may be had from the secretary of the association, Hamilton House, Bidborough Street, W.C.1.

Appointments

BALLARD, S. I., L.R.C.P.E.: medical superintendent, Isle of Man Mental Hospital.

FREEMAN, PEARL, M.B. Glasg.: asst. M.O., Oldbury.

LISHMAN, F. J. G., M.D. Lond., D.P.H., D.L.O.: senior M.O., Essex.

MADDOCKS, S. A., M.R.C.S., D.M.R.E.: radiologist, Hillingdon County Hospital, Middlesex.

MICHIE, WILLIAM, M.B. Aberd., F.R.C.S.E.: asst. surgeon, Aberdeen Royal Infirmary.

NICHOLAS, C. P., F.R.C.S.: surgeon, Evelina Hospital, London.

ROBERTSON, J. M., M.B. St. And.: junior asst. pathologist, The Victoria Infirmary of Glasgow.

STEWART, A. S. R., M.B. Glasg.: asst. physician, County Hospital, Ashton-under-Lyne, Lancs.

WARD, J. A., M.R.C.S.: M.O., Tanganyika, Colonial Service.

The Royal National Throat, Nose, and Ear Hospital, London:

Assistant Surgeons:
DOEY, W. D., B.A., M.B. Camb., F.R.C.S., D.L.O.
ROTTER, K. G., M.B. Lond., F.R.C.S., D.L.O.

Diary of the Week

DEC. 7 TO 13

Monday, 8th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. W. F. Harper: Anatomy of the Nose and Paranasa Sinuses.
5 P.M. Prof. R. Hare: Source and Transmission of W Infection.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Prof. John Ryle: Teaching and Research in Socia Medicine.

Tuesday, 9th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Sir Arthur MacNalty: Medical Department of the Loca Government Board. (First FitzPatrick lecture.)
ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. E. L. Patterson: Elbow Joint.
5 P.M. Dr. L. Foulds: Development and Limitation of Mali nancy, (i) experimental pathology.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Psychiatry.* Miss Anna Freud, Dr. Clifford Scott, Dr. D. W Winnicott, Dr. John Bowlby: Aggression in relation t Emotional Development.
5.30 P.M. *Experimental Medicine.* Dr. R. A. Kekwick, Dr. N. E Martin: Plasma Protein Fractions.
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende: pathological demonstrations.
CHELSEA CLINICAL SOCIETY
7 P.M. (South Kensington Hotel, 47, Queen's Gate Terrac S.W.7.) Mr. T. A. Cockburn, F.Z.S.: Treatment of Diseas in Wild Animals.
MIDDLESEX COUNTY MEDICAL SOCIETY
3 P.M. (Ashford County Hospital.) Dr. K. D. Keele: Disease of the Abdominal Aorta and its Branches. Dr. A. G Signy, Major B. E. Tomlinson: *Chronic Appendix.*
EDINBURGH POST-GRADUATE BOARD FOR MEDICINE
5 P.M. (Royal Infirmary.) Dr. D. M. Horstmann (Yale University Epidemiology of Poliomyelitis.

Wednesday, 10th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. F. Wood Jones, F.R.S.: Perineum.
5 P.M. Dr. Foulds: Development and Limitations of Malignancy (ii) clinical applications.
ROYAL SOCIETY OF MEDICINE
5 P.M. *Comparative Medicine.* Dr. P. H. Gell, Mr. H. B. Parry M.R.C.V.S.: *Nutrition and Resistance to Infection.*

Thursday, 11th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Sir Arthur MacNalty: Foundations of the National Health Service. (Last FitzPatrick lecture.)
ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. G. A. Harrison: Interpretation of Tests of Renal Efficiency.
5 P.M. Prof. R. J. V. Pulvertaft: Pathology of Poliomyelitis.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Portland Place, W.1
7.30 P.M. Dr. J. L. McLetchie: Control of Sleeping-sickness in Nigeria.
INSTITUTE OF DERMATOLOGY
5 P.M. Dr. H. W. Barber: Lichen Group of Eruptions.

Friday, 12th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. Harrison: So-called Acid-base Blood Balance.
5 P.M. Prof. W. D. Newcomb: Gastric Ulcer and Carcinoma.
ROYAL SOCIETY OF MEDICINE
8 P.M. *Radiology with the Faculty of Radiologists and the British Institute of Radiology.* Mrs. E. K. Dawson, Prof. R. W. Scarff, Mr. R. B. C. Ledlie, Sir Stanford Cade: Carcinoma *of the Breast.*
LONDON CHEST HOSPITAL, Victoria Park, E.2
6 P.M. Mr. J. W. S. Lindahl: Sinus Infection in Chest Diseases.
ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh
8 P.M. Prof. R. W. B. Ellis: Effects of War on Child Health.

Saturday, 13th

ROYAL SOCIETY OF MEDICINE
10 A.M. *Radiology with the Faculty of Radiologists and the British Institute of Radiology.* Dr. R. McWhirter, Dr. Clemmesen *(Copenhagen)*: Carcinoma of the Breast.
BIOCHEMICAL SOCIETY
11 A.M. (London School of Hygiene, Keppel Street, W.C.1.) Symposium on the Biochemical Reactions of Chemical Warfare Agents.

THE British Medical Association Handbook for 1947–48 contains in compact form useful information about the officers, membership, constitution, and *publications* of the association, and it also summarises the more important decisions of the representative body upon matters of policy.

THE address of the home division of Messrs. Burroughs Wellcome & Co. will be 183–193, Euston Road, London, N.W.1 (Euston 4477), from Dec. 15. The same address will apply to their overseas division from Dec. 21.

BSORPTION OF PENICILLIN GIVEN BY MOUTH

H. C. STEWART
A., M.D. Camb., Ph.D. Lond.
ECTURER IN PHARMACOLOGY
AND THERAPEUTICS

J. R. MAY
B.A., M.B. Camb.
ASSISTANT CLINICAL
PATHOLOGIST

ST. MARY'S HOSPITAL, LONDON

From the Department of Physiology and the Inoculation Department of St. Mary's Hospital, London

AMONG the few disadvantages of penicillin therapy is e very uncertain response of infections to treatment th the drug given by mouth, as compared with the ccess of sulphonamides by that route. The first tempt to administer penicillin in this way was reported Abraham et al. (1941), but little has since been pubhed in this country on the subject, perhaps because e impression obtained from many of the earlier reports s that the only factor concerned in the failure of the thod was the destruction of penicillin by the acid in e stomach, a view which is still widely held. Various alis have been used to combat the acidity of the gastric ice, but the results have been equivocal and rarely bstantially better than when alkalis were not used. no case have the blood-levels obtained been so high those constantly found after intramuscular injections the same doses. The final doubt was thrown on the ggestion that acid was the only factor by McDermott al. (1946), who showed that no better absorption was tained with penicillin by mouth in patients with hlorhydria.

In many of the reports the information obtained out the absorption of penicillin given by mouth has me largely from cases under treatment. Many of se, however, were cases of gonorrhœa (Paul et al. 45, György et al. 1945), the causal organism of which one of the most sensitive to small concentrations of nicillin. Since the doses given by mouth in these ses were very large, it is not surprising that the results re good, even though only a small fraction of the se may have been absorbed.

In the present investigation we have tried to determine e relative importance of the factors governing the sorption of penicillin given by mouth. No attempt s made to treat actual infections; all the results were tained in normal healthy adults, most of whom were n of 20–40 years. It has been shown by Henderson d McAdam (1946) and Buchanan (1946) that babies der 6 months of age may absorb penicillin by mouth tter than adults, but we have not investigated this point.

In all the experiments described below, except when odenal intubation was adopted, the volume of water used for the administration of the penicillin was about 120 ml. or 4 oz. (half the capacity of a 250 ml. beaker). This amount was a reasonable compromise, because, while it did not dilute the penicillin unduly, it was sufficient, it was hoped, to allow the dose to pass rapidly through an empty stomach and to lessen the taste of the penicillin, which some subjects found obnoxious.

Sublingual penicillin had been tried before but proved unsatisfactory, mainly because of the extremely disagreeable taste, which gave rise to copious salivation and made it impossible to retain the tablet in situ for more than a few seconds. Now that purer penicillin with a less obnoxious taste was obtainable it was found possible to keep 15,000 units/0·15 ml. under the tongue for fifteen minutes without swallowing. Out of 8 experiments in 5 persons, only 2 gave a blood-penicillin level in one specimen in each case, the rest showing no absorption. This was not, therefore, considered a practical method.

TABLE I—EFFECT OF FOOD ON PENICILLIN ABSORPTION

ll readings were the highest obtained after 15,000 units of penicillin had been taken. Blood was tested at 20 min., 40 min., 1 hour, hours, and 3 hours after administration of penicillin.

ESTIMATION OF PENICILLIN

In Blood.—In the early experiments the method used for estimating blood-penicillin levels was that described by Fleming (1944), using hæmolysis of blood by a streptococcus as the indicator. Subsequently Fleming and Smith (1947) improved this method by substituting a mixture of glucose, phenol red, and serum water for the saline diluent and red cells. This method was used for the experiments in the latter half of our investigation.

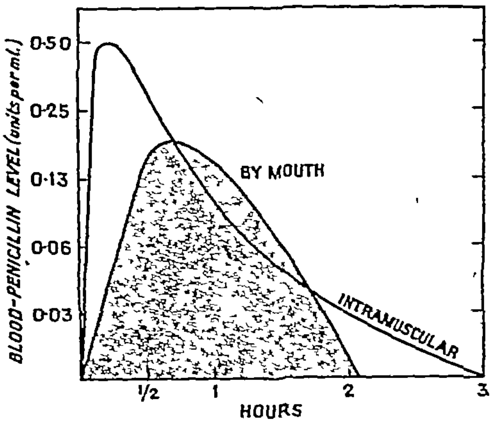

Fig. 1—Variation in absorption (shaded area) observed in 16 persons after a dose of 15,000 units of penicillin by mouth on an empty stomach, compared with a typical curve of blood-penicillin levels produced by the same dose of penicillin given intramuscularly.

In Urine.—The penicillin content of the urine specimens was estimated on agar plates by the filter-paper disc method, with the Oxford H staphylococcus as the test organism.

Other methods used are described with the relevant experiments.

EFFECT OF FOOD

It was necessary first to ascertain whether penicillin should be given on an empty stomach—i.e., whether food in the stomach interferes with absorption. If so, it was essential to know what interval should elapse between the taking of food and the administration of the penicillin.

For this purpose 12 persons each swallowed 15,000 units of penicillin on five separate occasions at different times in relation to food. This dose is small in comparison with those recommended for therapeutic use by mouth; but, since the penicillin was not being used for treatment, there was no object in giving a bigger dose. Further, with a small dose it is easier to appreciate small differences of absorption in relation to food, while at the same time it is easier to differentiate the good from the bad absorber.

The penicillin was given on an empty stomach; with food; and one, two, and three hours after food. It was impracticable, under present conditions, to control the type of food eaten, but by giving the penicillin in relation to breakfast this difficulty was to some extent obviated, since

Pan-American Congress of Ophthalmology

Among the guests who are to address the third Pan-American Congress of Ophthalmology, which is to be held in Havana from Jan. 4 to 10, are Sir Stewart Duke-Elder whose subject will be Penicillin in Ophthalmology, and Dr. Elizabeth Cass (Gibraltar) who will speak on Strabismus.

Deferred Call-up of Laboratory Trainees

Under an arrangement announced by the Ministry of Health, trainee laboratory technicians may apply for deferment of call-up until their training has been completed. Deferment is to be granted subject to provisos as to age, suitability of the training provided, and satisfactory progress in training.

Royal Society of Arts

On Monday, Jan. 26, Dr. C. H. Andrewes, F.R.S., will speak on Progress in the Fight against the Common Cold, on Feb. 2, Prof. A. C. Frazer on the Metabolism of Fats, and on Feb. 9, Sir Jack Drummond, F.R.S., on Fats in the Life of the Nation. All these Cantor lectures will be given at the house of the society, John Adam Street, Adelphi, London, W.C.2, at 4.30 P.M.

Middlesex Hospital Arts Society

This society is holding their annual exhibition in the board-room of the hospital, London, W.1, on Dec. 15-18, from 11 A.M. to 6 P.M. (4 P.M. on the 17th). One of the main sections will be work by members of the Photographic Society, and Prof. J. McIntosh and Dr. K. B. Merling will show electron photo-micrographs, and Mr. W. H. S. Cheavin, F.R.M.S., philatelic research by X rays.

Chairmanship of Food Investigation Board

Sir Frank Engledow, F.R.S., Draper's professor of agriculture in the University of Cambridge, has been appointed chairman of the board in succession to the late Sir Joseph Barcroft, F.R.S. The board, which has research stations at Cambridge, Aberdeen, and East Malling, Kent, is concerned with the conduct of research into the properties and behaviour of foodstuffs, and the scientific problems involved in their storage and transport.

Ling Physical Education Association

A conference on remedial gymnastics will be held at Sloane School, Hortensia Road, Chelsea, S.W.10, from Monday, Dec. 29, to Friday, Jan. 2. The aim of the conference is to emphasise the importance of the prevention and cure of minor defects in school-children; to stimulate interest in the specialised treatment of those more seriously handicapped; and to give a picture of medical gymnastics as carried out in this country. The medical speakers will include Dr. Harold Balme (Place of the Remedial Gymnast in the National Health Scheme), Dr. Doris Baker (Postural Foot Defects), Prof. A. B. Appleton (Feet and Posture), Dr. F. S. Cooksey (Postural Defects of the Spine), Miss M. Forrester-Brown (Team Work in the Prevention and Cure of Postural Defects), Dr. J. L. Dunlop (Place of the Educational Gymnast in a School Health Service). Further information may be had from the secretary of the association, Hamilton House, Bidborough Street, W.C.1.

Appointments

BALLARD, S. I., L.R.C.P.E.: medical superintendent, Isle of Man Mental Hospital.

FREEMAN, PEARL, M.B. Glasg.: asst. M.O., Oldbury.

LISHMAN, F. J. G., M.D. Lond., D.P.H., D.L.O.: senior M.O., Essex.

MADDOCKS, S. A., M.R.C.S., D.M.R.E.: radiologist, Hillingdon County Hospital, Middlesex.

MICHIE, WILLIAM, M.B. Aberd., F.R.C.S.E.: asst. surgeon, Aberdeen Royal Infirmary.

NICHOLAS, C. P., F.R.C.S.: surgeon, Evelina Hospital, London.

ROBERTSON, J. M., M.B. St. And.: junior asst. pathologist, The Victoria Infirmary of Glasgow.

STEWART, A. S. R., M.B. Glasg.: asst. physician, County Hospital, Ashton-under-Lyne, Lancs.

WARD, J. A., M.R.C.S.: M.O., Tanganyika, Colonial Service.

The Royal National Throat, Nose, and Ear Hospital, London:

Assistant Surgeons:

DOEY, W. D., B.A., M.B. Camb., F.R.C.S., D.L.O.

ROTTER, K. G., M.B. Lond., F.R.C.S., D.L.O.

Diary of the Week

DEC. 7 TO 13

Monday, 8th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. W. F. Harper: Anatomy of the Nose and Paranas Sinuses.
5 P.M. Prof. R. Hare: Source and Transmission of Woun Infection.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Prof. John Ryle: Teaching and Research in Soci Medicine.

Tuesday, 9th

	Water Capsule	0·25 0·25	0 35 0 5	0·07 0 06	0·03 0	0 0	0 0

ven by mouth would therefore be indicated by the retion of about 10,000 units. Excretion of a smaller ount would indicate incomplete absorption.

The results of these experiments (fig. 2) show that the aimed penicillin, when administered a second time, e no better results than did the same dose of mercial penicillin in the control experiment.

CAPSULES

Penicillin in enteric-coated capsules has been used in e past to avoid the destructive effect of the gastric idity (Burke et al. 1945). Our experiments showed t the effect of pH was not very important and could ly have been overcome by the use of capsules designed disintegrate in the gut and not in the stomach.

To assess the value of this procedure, a few experiments re carried out on the best absorber in our series, who wallowed capsules with the same dose in each. These had been variously coated by formalin-hardening cess to dissolve some in 2–10 min., some in $1^1/_2$ hours, d some in 3 hours. These times were known from control experiments in which some of the capsules of each kind had been swallowed but barium sulphate had been substituted for penicillin and the dissolution time determined by radiography.

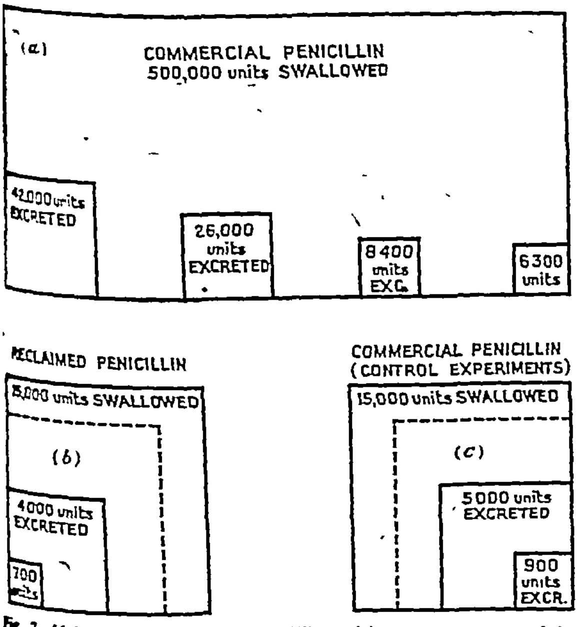

Fig. 2—Urinary excretion of penicillin: (a) amounts excreted by 4 persons after taking 500,000 units by mouth; (b) amounts excreted by 2 persons after taking by mouth a dose of 15,000 units of penicillin reclaimed from urine; (c) amounts excreted by same 2 persons after taking by mouth a dose of 15,000 units of commercial penicillin. The areas enclosed by the interrupted lines represent the approximate amounts that should have been excreted if all the penicillin had been absorbed.

The results (fig. 3) showed that blood-penicillin levels were progressively lower the farther down the gut the capsule dissolved. Since the best results were obtained with the untreated capsule, it was necessary to determine whether this method had any advantage over the administration of penicillin in water.

Six persons swallowed 100,000 units of penicillin on two occasions, the first in water and the second in an untreated gelatin capsule, in each case on an empty stomach. The results are shown in table v.

In view of all these results it is not surprising that the use of capsules has been abandoned.

PENICILLINASE

To investigate the relative importance of penicillinase among the various destructive factors in the intestine, samples were obtained of the bacterial flora at different levels in the gut. Any bacteria isolated were tested for the production of penicillinase after 24 hours' growth in nutrient broth. A penicillin-agar (2 units/ml.) plate, sown all over with Oxford H staphylococcus, was used. The solutions to be tested were placed in porcelain cylinders standing on the medium. The presence of penicillinase was shown by growth of staphylococci round the cylinders after incubation.

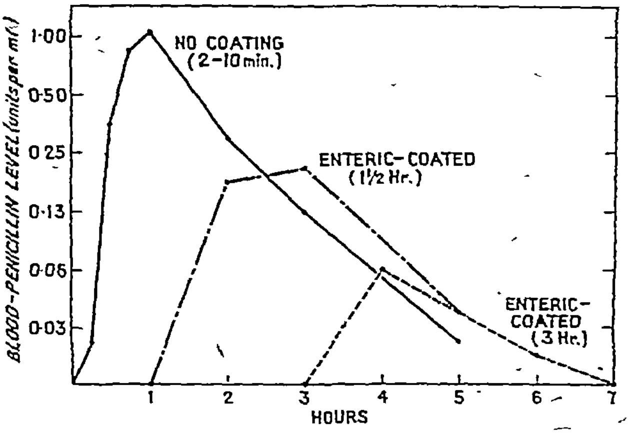

Fig. 3—Blood-penicillin levels obtained from a person who swallowed 100,000 units of penicillin on three occasions in gelatin capsules with different degrees of enteric-coating.

Two methods were adopted to obtain samples of gut contents: from the upper part of the duodenum by direct intubation (see below), and from the jejunum and ileum by the introduction and withdrawal of sterile nutrient broth through the gut-wall at operation, with a hypodermic syringe and fine-bore needle. Some collateral information was obtained by direct culture of the contents of the rat's intestine at various levels.

Results.—In 7 samples of duodenal contents no penicillinase-producing organisms were found. In 2 cases specimens were taken from about 2 ft. distal to the duodenojejunal flexure and about 3 ft. proximal to the ileocæcal junction. No penicillinase-producing organisms were found in either jejunal specimen or in the first ileal specimen. The second ileal specimen contained a coliform organism which produced only 2 units/ml. of penicillinase in twenty-four hours. Various organisms were cultured from different levels of the rat's intestine, but none produced penicillinase.

DUODENAL INTUBATION

Since the results obtained with enteric-coated capsules appeared to show that absorption of penicillin from the gut became progressively worse the farther down the

TABLE II—PENICILLIN STABILITY IN GASTRIC JUICE AT VARYING pH (SERIES I)

Gastric-juice specimen no.	Concentration of penicillin in buffer (unit/ml.)			
	A	B	C	D
1	0·75	0·06	0·06	0·04
2	1·0	0·25	0·25	0·18
3	0·75	0	0	0
4	0·75	0·25	0·25	0·25
5	0·75	0	0	0
Control	0·75	0·75	0·75	0·5

A, immediately after mixing.
B, after an hour at pH 3 or less.
C, after a further half-hour at pH 6–7.
D, after a further hour at pH 8.

this meal was the one which varied least. No food was allowed until two hours after the penicillin had been given.

Table I lists the highest blood-penicillin level for each of the 12 persons and for 4 other persons given penicillin on an empty stomach only.

Fig. 1 shows the variation in absorption in 16 persons who had each taken 15,000 units of penicillin by mouth on an empty stomach compared with a typical blood-penicillin curve produced by the same dose of intramuscular penicillin.

The highest blood-penicillin levels found in 9 persons who had taken 20,000 units of penicillin by mouth on an empty stomach were as follows:

Subject no. ..	1	2	17	18	19	20	21	22	23
Blood-level (u./ml.)	0·13	0·13	0·06	0·06	0·13	0·05	0·04	0·03	0·07

Blood was tested 20 min., 40 min., 1 hour, 2 hours, and 3 hours after administration of penicillin.

Since these results showed that the best absorption was almost always obtained when food was withheld, all subsequent experiments were performed on an empty stomach, except when the contrary is stated.

EFFECT OF pH OF GASTRIC JUICE

To assess the importance of the pH of the gastric juice, in-vitro experiments were carried out with juice of various acidities, instead of plain acid solutions, to imitate more closely in-vivo conditions. Three series of experiments were performed, the technique being basically the same in each; 2 ml. of each specimen of gastric juice was taken and 0·1 ml. of penicillin (1000 units/ml.) was added, making a final concentration of 50 units/ml.

Before each estimation a 10 c.mm. aliquot was taken and added to 1 ml. of nutrient broth. This diluted the penicillin to a strength suitable for titration and at the same time buffered the acid to a neutral and penicillin-stable pH. After the addition of the penicillin to the gastric juice all specimens were kept at a temperature of 37°C, from which they were not removed until the end of the experiment, and the removal of specimens for titration and their dilution in buffer were also carried out at this temperature.

In each series of experiments a control was prepared by mixing equal quantities of each specimen of gastric juice, and 2 ml. of this was adjusted with $N/10$ NaOH to pH 6– This specimen was then tested exactly as the others.

TABLE III—PENICILLIN STABILITY IN GASTRIC JUICE AT VARYING pH (SERIES II)

F, ,, 1 hour ,, ,, ,,

Series I

Five specimens of gastric juice were used, and the pH each with universal indicator was 3 or less.

Incubation was carried out for an hour at acid pH and th for half an hour at pH 6–7 after adjustment with alka and finally for a further hour at pH 8 after adding mo alkali. In this way a time greatly in excess of that in whic the penicillin could remain at these pH levels in the bod was covered.

Titrations were carried out immediately after mixin after an hour's acid incubation, after half an hour of neutralit and after an hour at pH 8. The results are shown in table II

Series II

Since the acid hydrolysis during the first hour from th above experiments was most important, further specime of gastric juice were investigated and specimens were take at short intervals during an hour's acid incubation only.

In this series the pH of each specimen was measured mo accurately with a glass electrode. The results are given table III.

Series III

Further specimens of gastric juice were selected to cov the less acid range not included in the previous series.

The pH of each of these specimens was also measure with a glass electrode. The results are given in table IV.

SELECTIVE ABSORPTION

Owing to the varied reports on the absorption penicillin given by mouth it was thought advisabl before proceeding further, to investigate the possibilit that penicillins I, II, III, and K might be absorbed t different extents. If this were so, differences in th content of these types in the different batches of com mercial penicillin might explain the very variable result reported by different workers.

TABLE IV—PENICILLIN STABILITY IN GASTRIC JUICE AT VARYIN pH (SERIES III)

Gastric-juice specimen no.	pH	Concentration of penicillin in buffer (unit/ml.)					
		A	B	C	D	E	F
9	2·0	0·5	0·25	0·175	0·125	0·1	0·04
10	2·9	0·5	0·5	0·5	0·5	0·35	0·25
11	4·2	0·5	0·5	0·5	0·5	0·5	0·35
Control	6·7	0·5	0·5	0·5	0·5	0·5	0·5

A, B, C, D, E, and F as in table III.

Because of the impossibility, when these experiments were carried out, of obtaining pure samples of the different penicillins for this purpose, the following experiment was designed.

Penicillin that had been excreted in the urine was extracted and readministered. This penicillin, been through the body once, should all be potentially absorbable; hence, if any selective absorption occurred, the urinary excretion of penicillin should be considerably greater after a dose of this reclaimed penicillin than after the same dose of ordinary commercial penicillin.

Four persons each swallowed 500,000 units of commercial penicillin which contained unknown quantities of the various types. The urine passed by each person during the next 24 hours was collected and the penicillin excretion estimated; all samples were then pooled and the penicillin extracted.

The total amount recovered was 70,000 units, which was only sufficient for four experiments using 15,000 units in each. It was therefore decided to select 2 persons (the best and the worst absorbers of the original 4), give each of them 15,000 units, and estimate again the total amount of penicillin excreted in the urine of each.

The excretion of penicillin after an intramuscular injection is about 60% of the original dose (Abraham et al. 1941, Rammelkamp and Keefer 1943). The amount of penicillin absorbed from a dose of 15,000 units

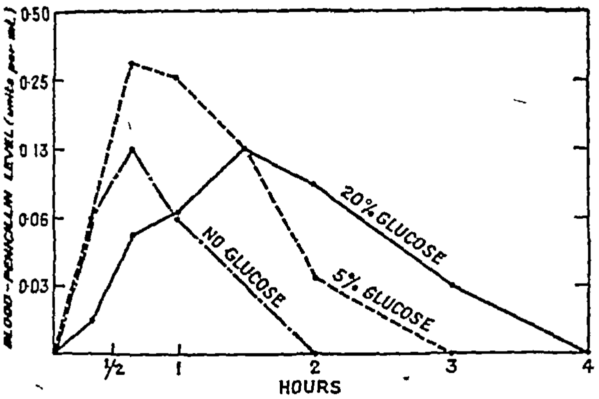

Fig. 5—Influence of glucose on absorption of penicillin in a good absorber.

instances, the remaining 2 being at one hour. Therefore, unless the pH of the gastric juice is less than 3, no significant destruction can be attributed to this factor by the time the peak of the blood-penicillin level is reached. Since the number of persons with a resting gastric pH of under 3 appears to be considerably less than the number of persons who absorb penicillin indifferently, it seems unlikely that destruction by acid gastric juice can be the only factor concerned. This supposition becomes even more tenable when it is realised that, during the first forty minutes after swallowing the penicillin, absorption is continually going on and thus the greater part of any dose cannot come in contact with the acid for anything approaching this length of time.

The question therefore remains whether the administration of alkali with penicillin is really advantageous. Finland et al. (1945) concluded that penicillin given in saline on an empty stomach gave blood-penicillin levels as good as those produced by any preparation incorporating antacids or buffers, with the possible exception of aluminium-hydroxide gel. This view is also in agreement with that of McDermott et al. (1945), who obtained blood-penicillin levels of the same order with penicillin in water, with or without antacid. György et al. (1945), however, found considerably higher blood-penicillin levels when sodium citrate was administered with the penicillin. From the results of our investigations it appears that an antacid would only be beneficial as such in preventing the gastric contents from being less than pH 3, which could only help in a limited number of cases. In this connexion, however, it should be remembered that slightly alkaline fluids traverse the stomach more readily than do acid or neutral fluids, and this fact is often utilised in dispensing irritant substances—e.g., digitalis and salicylates. The use of antacids or buffers, if given with penicillin, in a watery solution and not in capsules, may well help as much by facilitating the rapid entrance of the drug to the small intestine as by neutralising the gastric acidity.

Since absorption of penicillin is so rapid when it is given by mouth in water, a large proportion of the dose may well follow the lesser curvature of the stomach and mix little with its contents. If this explanation is correct, the choice of antacid becomes important. Those antacids which dissolve readily in water—e.g., sodium citrate and sodium bicarbonate—would be preferable for administration with penicillin in aqueous solution. The water-insoluble antacids—e.g., kaolin and magnesium trisilicate—adsorb the penicillin and tend to adhere to the gastric mucosa, which is obviously undesirable.

Capsules were often used in the early days; sometimes the penicillin was given by itself in this manner (Burke et al. 1945), and at other times it was incorporated in an oily base (McDermott et al. 1945). This method has now fallen into abeyance, partly because the capsules, enteric-coated to avoid the effects of gastric acidity, gave progressively worse blood-penicillin levels the farther down the gut they disintegrated (fig. 3), and partly because, even when they were not enteric-coated, with the result that they dissolved in 2–10 min., they still gave blood-penicillin levels no better than, and often inferior to, those given by penicillin in aqueous solution (table v).

The observation that blood-penicillin levels become progressively worse the farther down the intestine the drug is released is open to two possible explanations: there may be destruction by penicillinase; or the absorptive power of the intestinal mucosa may diminish progressively. As regards penicillinase, Wilson and Miles (1947) state that the bacterial flora of the normal gut consists of a few enterococci in the jejunum and increasing numbers of coliform and other organisms in the ileum. Our experiments showed that duodenal contents aspirated by tube in most cases contained no viable organisms, but such microbes as were cultured in no instance produced any penicillinase. Similarly in the jejunum no penicillinase-producers were found, and in the ileum 1 of 2 cases showed a coliform organism to be present which produced only 2 units/ml. of penicillinase in twenty-four hours under optimal conditions. It therefore seems most unlikely that penicillinase activity could play anything but a negligible part in the unsatisfactory results of giving penicillin by mouth.

The absorptive power of the intestinal mucosa was investigated in the experiments with duodenal intubation. The proximal part of the duodenum is well known to contain the optimal absorptive mucosal area for various substances. Experiments already discussed focused attention on this part of the gut; and, since the exact extent of this area is unknown, it was thought advisable to determine the influence that duration of contact between drug and mucosa in this area might have on the absorption of penicillin.

With doses that gave about the same blood-penicillin levels in different persons, experiments were carried out to determine the effect of giving the same dose of penicillin on two separate occasions to each person. The first time the dose was in a small bulk, 5 ml., and the second in a large bulk, 250 ml., of water. The idea was that the larger bulk would stimulate peristalsis and by gravity tend to leave the proximal part of the duodenum much more rapidly than would the small bulk; in which case the results should be better with the smaller bulk. This was found to be true (see fig. 4 and table vi). In subjects 1 and 13 the blood-penicillin levels obtained with the small bulk of fluid were comparable with those usually obtained with an intramuscular injection of the same dose.

Though only 5 persons were tested, the fact that the difference was of the same sign in each case is highly significant, even if the benefit from the cross-over test is ignored. Comparison of the small and large bulks, so far as maximal blood-penicillin levels were obtained, gave a mean of the difference of 0·16 unit/ml., with a standard error of ±0·09.

In a few cases penicillin was injected through the gut wall at operations for laparotomy or gastro-enterostomy. Since only one experiment could be done in each person, it was not thought to be a very practical way of obtaining evidence about the influence of bulk on the absorption of a given dose. However, in several cases very good blood-penicillin levels were obtained, suggesting that the condition of the patient and the anæsthetic had little inhibiting effect.

The possibility that any one type of penicillin might be better absorbed than another can be disregarded in the light of the experiments on selective absorption.

The use of glucose was disappointing. In several instances the blood-penicillin levels were higher and small intestine it was released, it seemed likely that the best absorptive area for penicillin, as for many other substances, was the upper end of the small gut. If this area was small, the length of time a solution of penicillin came in contact with it would be important. To test this assumption the following experiment was devised.

Five persons swallowed duodenal tubes on several occasions, and pairs of experiments were carried out on each: in the first a dose of penicillin was given through the tube in a small bulk (5 ml.) of water; and in the second, on a subsequent occasion, the same dose was given in a large bulk (250 ml.).

The object was to give the penicillin in such a bulk that on the first occasion it would tend to remain in the vicinity of the opening of the tube, whereas on the second occasion the increased amount of fluid would tend to pass rapidly along the gut. The only evidence accepted as proof of duodenal intubation was radiographical.

The larger volume of fluid was run in through a funnel by gravity, and the smaller was introduced with a syringe. Loss in the tube in the latter case was prevented by giving the penicillin in 2 ml. of water, washing through with a further 3 ml., and finally emptying the tube with 3 c.cm. of air, the volume of the tube.

Owing to individual variations in absorption each person was given by mouth test doses of penicillin in water on an empty stomach to select for use the smallest dose which would give blood-penicillin levels of the same order as those obtained from 15,000 units in a good absorber. In this way it was possible to average the different results, which are shown in fig. 4, where the results from penicillin by mouth are called control. The blood-penicillin levels obtained in each person in the various experiments are shown in table VI.

GLUCOSE

Since Armstrong et al. (1945) have shown that penicillin can be demonstrated in the blood for a longer time when injected intramuscularly in 5% glucose than when given in normal saline solution, we investigated the possibility that glucose might similarly affect penicillin given by mouth.

We carried out 73 experiments in 11 persons; 12 of these experiments were controls, the penicillin being swallowed in water instead of glucose solution. Only two doses of penicillin were used, 20,000 units and 100,000 units, and two glucose solutions, 5% (isotonic) and 20%.

Most of the experiments were carried out on an empty stomach, but in some persons a better result was obtained both in the control and in the glucose experiment when this was done two to three hours after taking food.

Ultimately, however, these experiments were abandoned because, though in some cases considerable improvement was shown, this was not a constant finding.

The beneficial effect was a longer maintenance of the blood-penicillin level as compared with the control, which was repeatable in the same subject but was not nece of any use in improving the blood-penicillin levels in a pe known to be a poor absorber.

One example of the effect in a glucose-sensitive subjec shown in fig. 5.

DISCUSSION

In the absorption of drugs from the alimentary t the buccal mucosa is the first possible portal of en The experiments in this connexion showed clearly t absorption through the buccal mucosa was of importance.

In the stomach there are two factors for considerati the effect of food, and the action of the gastric ju Burke et al. (1945) briefly investigated the influenc food on the absorption of penicillin and found t administration two hours after a meal gave better bl penicillin levels than half an hour after food. T workers in all their experiments recorded blood-penic levels greatly in excess of those recorded by any ot workers—even greater than the levels usually obtai after an intramuscular injection of the dose they u

From a therapeutic point of view it was essential know the relationship of penicillin absorption to f more exactly. Table I shows that, of 12 persons f tested, only 6 showed detectable blood-penicillin lev after the administration of 15,000 units in water mouth. Of these 6, only 1 had a measurable bloo penicillin level when the penicillin was swallowed eith with, or an hour after, food. At two hours after fo 4 of these persons showed blood-penicillin levels, incre ing to 5 persons at three hours. On an empty stoma —i.e., before breakfast in the morning or not less th four hours after a meal—with one exception (subject 1 all 6 subjects showed their maximal blood-penicill level. Besides this group of 12, 4 other persons ca swallowed the test dose on an empty stomach only 2 of these gave satisfactory blood-penicillin level showing that 8 out of 16 persons had absorbed measurab quantities of penicillin after taking 15,000 units. It interesting to compare this result with that in whic all of 9 subjects gave detectable blood-penicillin leve after swallowing 20,000 units on an empty stomac It seems, therefore, that blood-penicillin levels used an index of absorption indicate that 15,000 units is abo the median detectable dose.

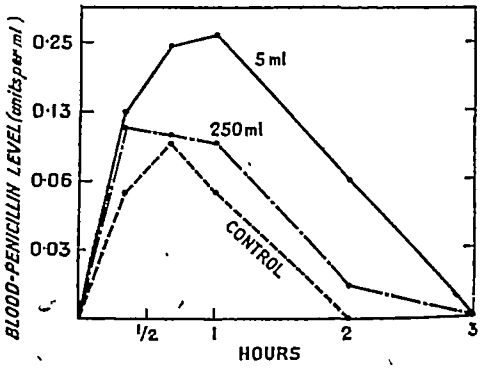

Fig. 4—Mean blood-penicillin levels of 5 persons detailed in table showing effect of fluid volume of dose on absorption of penic administered intraduodenally and of penicillin given by mouth a control.

The absorption of penicillin having been shown to b maximal in the absence of food, the influence of th resting gastric juice was next investigated. Table shows that the only destructive pH encountered in th alimentary canal is the acid one. Tables III and show that the pH must be less than 3 to produce an appreciable destruction of the penicillin in 40 min. Thi is important, because in 15 experiments in which peni cillin was swallowed by 6 persons the peak blood penicillin level occurred at or before this time in 1 further and destroyed the action of the tensores palati. Having been taken to pieces in this way, the palate was sutured in layers, allowing the soft palate to take a new, more posterior, position. The method is an application of the V–Y principle of plastic surgery, the soft palate being lengthened and brought nearer to the posterior pharyngeal wall.

If the child can be given a normal palatal speech mechanism—i.e., a normally shaped palate and a competent palatopharyngeal valve—the best time to repair the palate is before the child learns to speak. Speech can then be learnt by the ordinary imitative habits of childhood, and the bad habits and tricks of cleft-palate speech will not have to be unlearnt.

The results of this operation have been summarised by Wardill as follows:

> "It can be said that where the operation is done during infancy, and *where a functional palatopharyngeal valve has been formed*, speech will develop along normal lines without any training" (Wardill 1933).
>
> "Children operated upon by this method before the age of speech, assuming a successful surgical result, grow up in the large majority of cases as normal children, without any of the stigmata of cleft palate; and they require no speech training beyond what is customarily given to any normal child" (Wardill 1937).

We here describe the speech results in a consecutive series of 100 children whose cleft palates were repaired by one of us (F. H. B.), following the technique described by Wardill. The assessment was made primarily to learn our own results; but they may also be of use to practitioners and surgeons who have to advise on the treatment of these difficult cases. As Morley (1945) wrote:

> "Very few surgeons, even up to the present day, have published detailed accounts of the speech results of their operative procedures."

METHOD OF TREATMENT

The children were operated on in the Duchess of York Hospital for Babies, Manchester. A hospital such as this, with doctors and nurses experienced in nutritional disorders and the care of infants, is essential to the success of a cleft-palate centre. Skilled pædiatric care before and after operation makes possible a high standard of safety. It is a testimony to the care of our medical colleagues and the nurses, largely under the guidance of Dr. Catherine Chisholm and Dr. Sylvia Guthrie, that in 100 children coming to hospital for repair of the palate operation was never refused and no child died.

Age at Operation.—If the case was one of complete cleft, the lip and anterior palate were repaired by Veau's (1931) technique when the infant was 3 months old. The main palate operation was done at the age of 12–21 months.

Anæsthetic.—The anæsthetic consisted of intratracheal nitrous oxide, oxygen, and ether, given by Dr. K. B. Pinson, whose watchful care and great experience were in large part responsible for the good condition in which the infants left the operating-theatre.

Operation.—The technique followed that described by Wardill, except in two particulars:

(1) Instead of four short flaps of hard palate mucosa, one long flap of mucoperiosteum was raised on each side—as in the Veau and earlier Wardill operations—and the posterior palatine arteries were preserved. Careful freeing of the tissues round these vessels allowed them considerable mobility.

(2) Pharyngoplasty was performed in the first half of the series only; in the second 50 cases the posterior pharyngeal wall was not disturbed.

At the end of the operation it was seen that the anterior ends of the hard-palate flaps were now 0·75–1·0 cm. further back in the mouth than when they were first raised, a measure of the posterior displacement of the new soft palate. As the anæsthetic tube was withdrawn and the child gagged, it was seen that the soft palate could reach the posterior pharyngeal wall.

Assessment.—The children were examined 4–8 years after the operation, at the age of 5–9 years. Speech therapy had not been used. Each child had learnt to speak at home in the ordinary way. It was possible to determine whether the palatopharyngeal valve was competent by the absence of nasal escape or of nasal intonation during speech, by the child's ability to snort or to blow up a balloon, and by his ability to pronounce correctly the explosives K and G. It is well known, however, that a child may be able at the doctor's knee to demonstrate complete oronasal closure in any of these ways, and yet at home exhibit all the faults of cleft-palate speech. In this series some of the children whose speech was assessed as "imperfect" could say all the test words correctly and could blow up a balloon, but had obvious faults in continuous speech. For this reason, after investigating the condition of the palatopharyngeal valve, we took as our criterion in assessing the result the quality of speech when the child was talking with his parents or friends.

TABLE I—SPEECH RESULTS AFTER OPERATION FOR CLEFT PALATE

Type of cleft	Total	Speech perfect	Speech perfect except for minor hard-palate or lip faults	Speech imperfect	Imbecile
Postalveolar	41	27	8	4	2
Complete ..	49	19	18	11	1
Total ..	90	46	26	15	3

RESULTS

There was no death in hospital in this consecutive series of 100 children.

The soft palate remained totally united in all cases. In 12 cases a small perforation (up to 0·5 cm. in diameter) developed between the mouth and the nose at the tip of the hard-palate flaps.

Of the 100 children, 90 were examined; 6 of the missing children had died from accident, enemy action, or disease; 4 children could not be traced.

In 41 of the 90 children the cleft was postalveolar—i.e., of the soft palate, or of the soft palate and hard palate only, the alveolus being intact. In the remaining 49 the cleft was complete—i.e., of upper lip, alveolus, and palate, whether unilateral or bilateral.

Of the 90 children, about half (46) spoke perfectly, with no speech stigma of any kind; about a quarter (26) spoke perfectly except for small faults associated with irregularity of the anterior hard palate or lip; and about a fifth (18) spoke imperfectly (in 3 of these the operation could not be assessed, because the children were mentally defective). The results are shown in table I.

Speech Perfect

In the 46 children who spoke without stigma, tests for oronasal closure showed the palatopharyngeal valve to be competent.

A child was placed in this category only after a most critical examination. The description "perfect" meant that the speech was in every way indistinguishable from that of a normal child.

This speech result was obtained more often after repair of a postalveolar cleft than after repair of a complete cleft (table I), since with a complete cleft the alveolus is more likely to be deformed or the lip adherent, leading to difficulties in sound-production (see below).

It was notable in these children that the soft palate was long, mobile, and supple; and that the hard palate was smooth and regular in contour, with the teeth in maintained longer; but glucose did not produce a consistent improvement in poor absorbers. Nevertheless, from a therapeutic point of view, some caloric intake is essential, and for a few days at the height of an illness carbohydrate as a food source is all that is required. It is fortunate that this can be provided in a manner which, far from interfering with the absorption of penicillin, may improve it.

McDermott et al. (1945) have stated that, to produce blood-penicillin levels comparable with those following an intramuscular dose of penicillin, five times as much must be given by mouth. This appears to be a generalisation but does not distinguish between the good absorber and the bad. In our series, both for 20,000 units and 100,000 units, this relationship, even supposing that the increase in blood-penicillin level was proportional to the increase in dose, held good only for the good absorbers, who from a treatment point of view present little difficulty in any case. Ten times the intramuscular dose, however, seems to be a safer figure to ensure satisfactory results in both poor and good absorbers.

If penicillin is to be given by mouth, the following system is suggested. The penicillin should be given in about 4 oz. of 5–10% glucose solution, containing about gr. 20 of sodium bicarbonate or citrate, before meals, and not less than three hours, preferably four hours, after the previous meal. The dose should be ten times as great as the dose of intramuscular penicillin that produces the blood-penicillin levels required. If these are to be maintained continuously, a dose of 500,000 units by mouth should be satisfactory.

SUMMARY

To ensure the best possible absorption, penicillin by mouth should be given on an empty stomach.

There is no evidence that any of types I, II, III, and K penicillin is better absorbed than another.

In all instances the use of capsules gave results inferior to those obtained with the same dose in aqueous solution.

The destructive effect of gastric acidity is only of importance when the pH is less than 3.

Most of the penicillin is absorbed in the upper part of the small intestine.

Destruction of penicillin by penicillinase in the upper digestive tract is negligible.

Glucose is a convenient source of energy which can be given with penicillin and often enhances the result.

The most important factor influencing the absorption of penicillin seems to be the unexplained individual variations in the absorptive capacity of the gut.

We wish to thank Sir Alexander Fleming for his stimulating interest and encouragement; Dr. D. Rowley for the extraction of penicillin from urine; Drs. K. E. Cooper, K. W. Cross, and A. H. James for helping us by swallowing duodenal tubes; many others for acting as experimental subjects; Prof. C. A. Pannett, Mr. A. E. Porritt, and Mr. J. C. Goligher for certain specimens; and the Sir Halley Stewart Trust for their continued financial support to one of us (H. C. S.)

SPEECH AFTER REPAIR OF CLEFT PALAT

F. H. Bentley

O.B.E., M.D., B.Sc. Manc., F.R.C.S.

PROFESSOR OF SURGERY IN THE UNIVERSITY OF DURHA
FORMERLY SURGEON TO THE DUCHESS OF YORK HOSPITAL
FOR BABIES, MANCHESTER

Irmgard Watkins

Ph.D.

The importance of a cleft palate to the patient li in its effect on speech, and the ultimate criterion operative repair is the resultant speech. Operatio such as the Langenbeck, designed only to close th obvious cleft, do not provide one of the factors essenti for normal speech—a soft palate capable of reaching th posterior pharyngeal wall, so making possible comple oronasal closure. Passavant (1869) first described ho this closure was brought about, the soft palate risi upwards and backwards to reach a prominent ridge on th posterior pharyngeal wall caused by contraction of th superior constrictor muscle (Passavant 1869, Whil 1930); though more recently Townshend (1940) a Wood Jones (1940) have shown that the muscle-fibr concerned in this ridge are those of the palatopharyngeu

Since Passavant described the sphincteric action the hiatus nasopharyngeus there has been a gradu development in surgical practice towards an operati which does not merely close the cleft but also brin the soft palate nearer to the pharynx. Important stag in this development were the operations described Gillies and Fry (1921) and Veau and Borel (1931).

Veau aimed at reducing scar tissue to a minimum completely suturing the nasal mucosa as well as th buccal and by approximating the two halves of the sof palate musculature. In addition to reconstructing th palate in layers, he completely freed from the bone th long flaps of hard-palate mucosa, so as to allow them lie intimately against the bone in their new position. Th also permitted the soft palate to be more readily displac backwards into the pharynx. Of 100 children wh underwent this operation 62 acquired normal speech and of 47 of them operated on during the first two yea of life 34 (72%) acquired normal speech (Veau an Borel-Maisonny 1933).

Wardill (1927, 1928, 1933, 1937) emphasised th importance of the palatopharyngeal sphincter, or valv formed by the soft-palate muscles and those of th posterior pharyngeal wall. He drew attention to th continuous activity of the valve during speech, an demonstrated that, unless it was competent, productio of normal speech sounds was impossible. He showe further that in cases of cleft palate the bony pharyn was abnormally wide and deep, making it more difficul to construct a competent valve. To overcome thi anatomical handicap he introduced the operation o pharyngoplasty, in which a transverse incision was mad across the posterior pharyngeal wall at the level of th arch of the atlas, exposing the muscle-fibres which her descend in a distinct bundle on either side of the midline The wound was then sutured vertically, bringing togethe the two halves of the muscle, narrowing the pharyn from side to side, and producing a bulge of muscle in th region of the normal Passavant's ridge. An alternativ method of narrowing the nasopharynx was described b Browne (1934).

The repair of the palate described by Wardill include the best features of the Gillies-Fry and Veau operations Long flaps of mucoperiosteum were raised from the hard palate (in later operations four shorter flaps were used) the soft-palate muscles were completely freed anteriorly from their attachment to the posterior edge of the hard palate, and from the pharyngeal wall laterally. Fracture of the hamular process on each side freed the soft palate possible and the explosive sounds were good. The of operation was satisfactory, but speech remained as in the previous group, because of a disability of the central nervous system.

(3) *Imbecility* was found in 3 children in whom the structure of the palate appeared satisfactory, but it was impossible to carry out any tests.

We do not know whether this high incidence of mental deficiency is to be expected in any collection of children with cleft palates. Apart from these 3 children, mental backwardness was not conspicuous in our series. On the contrary, a feature of the children who spoke perfectly or almost so (three-quarters of the total) was their mental alertness and general brightness—conditions no less notable in their enthusiastic parents, who came gladly the follow-up clinics year after year, in many cases travelling long distances. There can be no branch of surgery more satisfying to the surgeon than cleft-palate reconstruction, which demonstrates the fascinating physiological result that follows a successful technique, and sees such gladness in parent and child.

PHARYNGOPLASTY

It is of interest to compare the function of the palatopharyngeal valve and the speech results in the series in which pharyngoplasty was performed with that in which it was not. The results obtained in 87 children in whom it was possible to assess the speech mechanism are given in table II.

The figures do not show much difference between the two groups. The aim of a pharyngoplasty is to facilitate closure of the palatopharyngeal sphincter. In all the cases in which pharyngoplasty was performed this closure was gained; and, though there were 5 imperfect speakers in the group, the cause of the imperfection was not in the palatopharyngeal valve. In the comparable group in which pharyngoplasty was not performed there were imperfect speakers, and in 2 of these the palatopharyngeal valve was at fault. These were the 2 cases described above) in which the soft palate was noted as being very small and posterior displacement at operation was inadequate. Possibly, if the pharynx had been narrowed by a plastic operation, the small soft palate might have become adequate to effect oronasal closure.

There was thus this small difference in our results in favour of pharyngoplasty. Examination of the pharynx in children in whom pharyngoplasty had been done showed a rather fixed and immobile posterior pharyngeal wall. By contrast, in the cases in which pharyngoplasty had not been done the posterior pharyngeal wall was mobile, with good contraction and elevation of its muscles. It was our impression that after pharyngoplasty the advantage gained by the narrowing was lost by the immobility that followed; whereas when the posterior pharyngeal wall was not disturbed it developed a mobility that compensated for the slightly greater diameter of the pharynx.

CONCLUSION

Wardill's operation aims to close the anatomical defect and to construct a competent palatopharyngeal valve on which speech depends. Wardill claimed that, if a normal palatal speech mechanism was provided at an early age, the child would speak normally without speech training.

In our results these claims are justified, for in only children was the palatopharyngeal valve incompetent. Without speech training, perfect speech was obtained in about half the cases, and in another quarter there was perfect speech marred only by slight articulatory defect due to irregularity of the anterior hard palate

The remaining cases (about a fifth of the total) showed various additional hazards such as gross deformity of the jaws, and defective speech sense—conditions not remedial by operation alone.

SUMMARY

A modified Wardill's operation was performed in 100 consecutive cases of cleft palate in children aged 12–21 months.

At follow-up examination about half the children had perfect speech; about a quarter had perfect speech except for minor faults due to irregularity of the anterior hard palate and alveolus; and about a fifth had imperfect speech, though only 2 had an incompetent palatopharyngeal valve.

Pharyngoplasty did not seem to produce better results.

TRILENE ANALGESIA

SIMPLE APPARATUS FOR SELF-ADMINISTRATION

J. T. HAYWARD-BUTT
B.A. Camb., M.R.C.S., D.A.
SENIOR ANÆSTHETIST, KING EDWARD VIII HOSPITAL, DURBAN

DURING the late war there was a great demand for a rapid and safe analgesic capable of use with no more than printed instructions. Early experience with assault landing troops showed that a satisfactory, though short, analgesia could be induced with a wool plug soaked in 'Trilene' in an ordinary 'Benzedrine' nasal inhaler. From these observations the present instrument was gradually evolved for the use of commandos, air, naval, and tank crews, and ambulance personnel, as well as to meet most of the normal medical requirements of trilene analgesia.*

Description of this instrument has been deliberately withheld for two years while it has undergone extensive trials both in Great Britain and in South Africa. The results have been so favourable that publication now seems justified.

DESCRIPTION

The inhaler (figs. 1 and 2) is of metal, $8^1/_4$ in. long and [illegible] in. in diameter, and weighs 10 oz. when fully loaded. It is designed on the principle of a cigarette lighter with an absorbent cotton-wool pad and a capillary wick leading trilene from a 6 ml. ampoule into a vaporising chamber seated in a nasal nozzle. This volume of trilene is just enough to saturate the pad without producing any fluid excess, and though sufficient for analgesia lasting 60–90 min. is insufficient to produce anæsthesia. The inhaler is brought into use by breaking the base of the ampoule with a spring plunger.

The component parts of the inhaler consist of (1) a plated brass tube with an internal screw thread at either end; (2) a plated brass cap at one end; (3) a plug at the other end fitted with a projecting spring plunger to prevent leakage of trilene; (4) a spring coiled round the plunger and the neck of the ampoule to hold it in place; and (5) the vaporiser unit, which screws into the cap end of the inhaler and bears a hollow nasal nozzle tapered to fit any nostril. The nozzle can be unscrewed for cleaning and sterilisation. The other good position. The operation had produced normal anatomical structure of soft and hard palate; the consequence was normal speech.

---

* Though the original work was done in England, experience showed that modifications in design were desirable, and the final instrument described here was manufactured by J. G. Dalton (Pty.) Ltd., Johannesburg, who now market it under the name 'Trilite Inhaler.' Imperial Chemical (Pharmaceuticals) Ltd., Manchester, also played a large part in its development by providing the accurate ampoule charges of trilene on which the instrument depends.

Speech Perfect except for Small Faults

In all these 26 children the palatopharyngeal valve was competent and the consonants G and K were spoken perfectly. There was no nasal escape or nasal intonation in their speech. There were, however, minor faults associated with deformity of the anterior palate or of the lip.

Anterior palate faults were found in 20 of the children, who had small imperfections in the sounds which are modified in the anterior palate and alveolar region, such as S, T, TH, D. The effect was to produce a slight lisp. The fault had an anatomical basis. Behind the incisor teeth the anterior hard palate was irregular, and the arch of the palate was unduly high owing to the repaired palate having fallen in a little towards the nasal cavity. An actual perforation at this site was found in only 4 instances.

In other cases the alveolar curve was triangular rather than rounded, or the alveolar ridge was irregular in contour, owing to malposition of the premaxilla. As a result of this unevenness the teeth were irregularly placed, sometimes very much so. These anatomical faults were naturally more common in cases of complete cleft (table I).

The operation had provided a competent palatopharyngeal valve, and the speech result of the soft-palate repair was excellent. The deformity of the anterior palate remained, however, as a cause of slight imperfection. It is difficult to see how the anterior palate and alveolar region could be repaired differently. The method aims at separate and complete nasal and buccal closure in this region, but the absence of bony palatal processes in the line of cleft leaves a tendency for the repaired mucosa to fall in towards the nasal cavity. If the cleft is wide, the two halves of the hard palate will tend to fall together, with consequent malposition of the alveolar regions. Irregularity of dentition follows.

If operative ingenuity cannot solve this problem, much might be done by orthodontic treatment. Prof. F. W. Wilkinson, director of the Dental Hospital, University of Manchester, who joined in the review of this series of cases, was emphatic that orthodontic measures could largely prevent this secondary deformity and cause the anterior palate and alveolar ridge to take up a correct position during the important early years of life.

If it is agreed, therefore, that a high level of achievement in cleft-palate surgery depends first on pædiatric skill, it should be added that final success requires the coöperation of the orthodontist. In the light of this experience we urge that, in the postoperative care of children with cleft palate, the orthodontic department should take a full share in the routine follow-up, so that any avoidable deformity can be prevented, and blemishes in speech reduced to a minimum.

Lip faults were found in 6 children, who had some difficulty in producing a normal F, V, M, P, or B. These were all cases of complete cleft, with tightness of the upper lip and adhesion of the lip to the alveolus. The deformity was greatest where the cleft had been wide and the lip elements small. The only surgical remedy seems to be to repair the lip afresh as the child approaches adolescence, when the soft tissues will be larger and more supple.

It is true that in both these types of minor defect speech therapy could correct the faults, even in the presence of anatomical deformity. If, in the search for a perfect repair, the surgeon appears to deny the presence of his ally, the speech therapist, it is only because of his insistence that normal function depends on normal structure. Wardill has said: "It should be the aim o every surgeon who is dealing with these cases to put th speech trainer out of work." Owing to the very natur of the problem, however, there must remain a residuu of cases in which the surgeon's aim is not achieved and where only the labours of the speech therapis can cause the child to speak perfectly.

Speech Imperfect

In 18 children there were more serious speech fault due to various causes: gross deformity of the jaw incompetent palatopharyngeal valve, defective speec sense, nervousness and stammering, and imbecility.

(1) *Gross deformity of the jaws* was found in 8 childre all cases of complete cleft, with considerable unde development of the maxillæ and imperfect alveol ridges and dentition; associated with this deformit was "overbite" of the lower jaw, causing severe ma occlusion. The soft palate in these cases was long an mobile, and the palatopharyngeal valve was competent The explosive sounds were excellent, but there wer gross faults in all other sounds, with lateral air escape.

These faults in speech were not related to the cle of the palate or to its repair, but to the grossly abnorma condition of the jaws. Such deformities and speec troubles occur in children whose palates are intac though they are to be expected more often in the con genital maldevelopment that leads to a cleft palat

TABLE II—SPEECH RESULTS WITH AND WITHOUT PHARYNGOPLASTY

—	No. of cases	Perfect speech or minor hard-palate or lip faults	Imperfect speech	Incompetent palatopharynge valve
With pharyngoplasty	41	36	5	0
Without "	46	36	10	2
Total ..	87	72	15	2

The palatopharyngeal valve was competent in all the cases, and therefore it could be expected that by combination of orthodontic treatment and speech therap normal speech would be possible.

(2) *Incompetent palatopharyngeal valves* were foun in 2 children, whose soft palate at operation was ver small and, in spite of extensive freeing of the soft tissue could not be approximated to the posterior pharynge wall. The operation note in these two cases foreca a poor speech result, and such was the outcome. The palatopharyngeal valve was incompetent; consequentl there was nasal escape during speech, and the variou tricks of cleft-palate speech were present. Operation ha failed in its aim because of insufficient material wit which to make the anterior part of the palatopharynge valve. Such a shortage of palate tissue occurred only twice in 100 operations, a sufficiently rare occurrence t justify the routine operative procedure.

(3) *Defective speech sense* was found in 5 children aged 6–9, in whom the palatopharyngeal valve wa competent and the explosive sounds were good, but formation of words was lacking. By their habits, manner, and appearance the children did not seem to be mentally backward, and from the condition of the palate norma speech would be expected; but coördinated speech wa completely lacking, and though the children could repeat all test sounds correctly they appeared to be lost when asked to repeat words.

The aim of the operation—complete oronasal closure—had been achieved in these children. Normal speech would only be possible, however, if the defective speech sense could be made good.

(4) *Nervousness and stammering* were found in children. In both of them complete oronasal closure

Scher's (1946) figures for his 521 cases are good. 7% fair, and 9% none. Barratt and Platts obtained successful results in 85% of their cases, also noted a high failure-rate in opening whitlows; r success rate in midwifery was 86·5%. Hill (1944) eed satisfactory analgesia in 87% of his 62 patients. e Ellingham (1944), using Hill's machine for dentistry, rather more successful with 5 failures in 100 cases.

t appears, then, that whichever machine is used, in y 100 cases trilene can be expected to produce a pletely successful analgesia, often with amnesia, in ases, partially to alleviate the pain in a further 9 or and to fail completely in the remaining 5 or 6 cases.

ig. 3—Inhaler in use.

The inhaler described here does possess some advantages over the other machines, apart from the results obtained.

Its small size ($8^1/_4 \times {}^7/_8$ in.) and lightness (weight when fully loaded 10 oz.) allow it to be easily carried in the pocket, in a corner of one's bag, or in a first-aid kit. In contrast to other machines, it is virtually unbreakable. When fully charged, the spring holds the ampoule rigidly in place, and this can only be broken by striking the plunger firmly. Provided this is not done, the charged inhaler will withstand any amount of rough handling.

Once the inhaler is charged with an ampoule it is always ready for use, and provided that the ampoule is unbroken inhaler may be left unused indefinitely but is ready n required. This is of particular importance when ms part of a first-aid kit. If the inhaler is used only ly a new charge should always be inserted after use. is used frequently this is not so necessary provided remembers that the life of a single charge is 60–90 ates of *active use. The cap should always be* aced after use, and if this is done a partially nded charge will remain soaked in the absorbent

he inhaler is used in a similar way to the familiar l inhalers, *and, if the patient is told this, it will* orrectly used at once. It can be issued as part of a aid kit in mines, ambulances, factories, &c., with implest of printed instructions. Anæsthesia cannot, ourse, be self-induced with the inhaler.

he 6 ml. ampoule of trilene has itself several advans over the larger bottle from which other machines filled. It prevents waste, provides a constant charge ch will produce analgesia for a known period, prevents by evaporation, and obviates any risk of deterioon. The ampoule is robust; when in the inhaler it been flown at a height of 10,000 ft. and tested in laboratory at a pressure equivalent to a height of 00 ft. without damage.

SUMMARY

simple, compact, unbreakable instrument is described the self-administration of trilene. It is designed to uce analgesia only and to be operated on the simplest ted instructions. It cannot self-induce anæsthesia is therefore suitable for use by unskilled personnel mines, ambulances, factories, and first-aid parties in eral. It is equally suitable for use in planned minor gery, dentistry, midwifery, &c.

t has been tested by 37 of my colleagues in 1183 cases prising 67 different painful conditions. Analgesia s "good" in 85% of cases, "fair" in 9%, and in 6% failed to develop at all. This efficiency is equal to that attained with larger and more complex machines.

I am indebted to Dr. C Langton Hewer, senior anæsthetist to St. Bartholomew's Hospital, London, and to Imperial Chemical (Pharmaceuticals) Ltd. for much helpful advice in the early stages of the development of this instrument; to my many colleagues who have been responsible for its clinical trials; to Mr. C. Whysall for the photographs; and to Dr. J. C. Thomas, senior pathologist, Natal Provincial Administration, for help in preparing this paper.

HOLT'S DIPHTHERIA TOXOID (P.T.A.P.)

Al PO_4 CONTENT, PURITY, AGEING, AND DURABILITY OF IMMUNITY

GUY BOUSFIELD
M.D. Lond.
With a note by L B. HOLT, M SC.

PRELIMINARY investigations showing the importance of using enough aluminium phosphate in the preparation of Holt's purified toxoid, aluminium-phosphate precipitated (P.T.A.P.), were reported previously,[1] when it was indicated that other work on the same lines would be undertaken.

Two further sets of P.T.A.P. samples, with different mineral carrier contents, prepared by Mr. L. B. Holt, were investigated under the same conditions as previously described—i.e., on Schick-positive children aged 1 year, partly in the same localities. In all cases single intramuscular injections of 0·5 ml. of P.T.A.P. were given, the Lf dosage of toxoid being kept constant at 5 units. The only variable factor in the different bottles was the concentration of aluminium phosphate. The effects of these single injections were studied by means of post-Schick tests 28 days later.

The first set of samples in this new series of observations were prepared from a relatively impure toxoid, batch E.2875, containing 10 Lf units per ml. and Al PO_4 in amounts of 3, 5, 7, 9, 11, 13, and 15 mg. per ml. The work was started when the samples were freshly prepared, but there were three bottles of each Al PO_4 concentration, a fact which will later be shown to have yielded some useful information.

TABLE I—SCHICK-CONVERSION RATES YIELDED IN 586 CHILDREN AGED 1 YEAR BY RELATIVELY IMPURE TOXOID, BATCH E 2875. DOSE 0 5 ML. CONTAINING 5 LF UNITS OF TOXOID (60% PURE IN TERMS OF PROTEIN)

Sample	Dose of Al PO_4 (mg.)	Post Schick results		Conversion-rate (%)
		Positive	Negative	
H3	1·5	10	69	87·3
H5	2·5	4	79	95·2
H7	3·5	6	76	92·7
H9	4·5	5	80	94·1
H11	5·5	6	79	92·9
H13	6·5	3	81	96·4
H15	7·5	2	86	97·7

The results obtained from using all three bottles of each Al PO_4 concentration are given in table I. It appears that the differences in the amounts of Al PO_4 in the seven samples were too small to produce a clear-cut curve, but the results given by the extremes H3

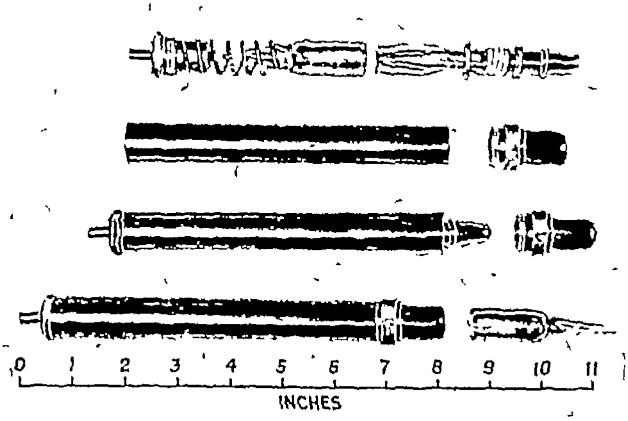

Fig. 1—Components of inhaler.

end of the vaporiser unit is tapered to pierce the base of the ampoule when necessary.

METHOD OF USE

The inhaler is loaded by unscrewing the plug, inserting a standard trilene ampoule, base foremost, and replacing the plug. The inhaler is now ready for immediate use, but it may be stored indefinitely without deterioration.

For use, the spring plunger is sharply struck against any rigid object, thus breaking the base of the ampoule against the tapered end of the vaporising unit. The inhaler is then held with the nozzle downwards for 5–10 sec., whereby the whole charge is absorbed and the wick draws trilene into the vaporising chamber. The cap is then removed, and the patient told to place the nozzle in one nostril, close the other nostril by finger pressure (fig. 3), and breathe normally in through the nozzle and out through the mouth. If the patient breathes out through the nozzle the direction of airflow is reversed and trilene wastefully blown out of the inhaler. Alternatively the nozzle may be inserted into the mouth. The patient is told to breathe normally until the pain disappears. Full analgesia is usually established with some twenty inhalations (about a minute). When analgesia has been induced, use of the inhaler is discontinued until pain begins to return, whereupon a further four or five inhalations of trilene reinduce analgesia.

A single ampoule is usually enough to maintain analgesia for 60–90 min. The patient, who is conscious throughout, is told to report any indication that the charge of trilene is becoming exhausted. The charge can be renewed in a few seconds by unscrewing the plug, removing the empty ampoule, tapping the inhaler gently to remove the broken glass fragments, and inserting a fresh ampoule.

When analgesia is required, the patient is told to breathe until a slight tinnitus or other subjective sign of analgesia develops. A further five or six breaths wi then produce full analgesia, which can be maintain either by easy continuous or intermittent inhalatio If the inhaler is used for only a short time the cap shou be replaced, and the inhaler can then be used agai but it is safer to leave the inhaler charged with unbroken ampoule. One is then always certain that t instrument is ready for instant use however long it h been put aside.

ANALGESIA PRODUCED BY THE INHALER

Type of case	No. of cases	*Analgesia*		
		Good	Fair	None
		%	%	%
Surgical, excluding whitlows	532	454 *(85·4)*	49 *(9·2)*	29 *(5·4)*
,, whitlows	26	12 *(46·2)*	8 *(30·8)*	6 *(23·0)*
Medical	38	33 *(86·8)*	4 *(10·5)*	1 *(2·6)*
Gynæcological (operative)..	65	50 *(76·9)*	9 *(13·8)*	6 *(9·3)*
Labour (normal and forceps)	116	100 *(86·2)*	11 *(9·5)*	5 *(4·3)*
Obstetric (other procedures)	105	97 *(92·4)*	4 *(3·8)*	4 *(3·8)*
First-aid	301	256 *(85·1)*	22 *(7·3)*	23 *(7·6)*
Total ..	1183	1002 *(84·8)*	107 *(9·0)*	74 *(6·2)*

The patient's subjective and objective reactions a the type of analgesia produced with this inhaler diff in no way from those produced with other apparat (Scher 1946).

RESULTS

This inhaler has been tested by a number of colleagues in various hospitals in South Africa Great Britain. Detailed reports have been rece on 1183 cases in which the inhaler was used for different painful conditions (see table). Of the analgesia was assessed as "good" in 1002 cases (85 "fair" in 107 (9%), and "none" in 74 cases (6 That is, analgesia was established in 94% of cases failed to develop in 6%. The failures were mainly Bantu patients whose coöperation is not easily obtaine

It has already been shown that trilene analgesia is effective with the most severe degrees of pain. T is strikingly illustrated by the incidence of failures dur the incision of whitlows (23%) compared with 5·4% of failures in all other surgical procedures. T inhaler was used satisfactorily by unskilled person as a first-aid measure in 301 cases of burns, fractu sprains, and abdominal, lacerated, and crushing woun In hospitals, one of its main uses is in the wards and outpatients' department when painful dressings are bei done. In the 300 cases of this kind reported the failu incidence was very low (3·7%).

Reports on the use of the inhaler in *midwifery* into two groups. There was first the series of 221 ca in the table, made up of 98 cases of normal labour, of forceps delivery, and 105 of other obstetric procedure which included 18 episiotomies, 15 manual remova of the placenta, 25 perineal repairs, 37 ruptures membranes, 4 rotations or versions, 3 cases of prolapse limbs, &c., 1 craniotomy, and 2 cases of eclamps It is notable that though in the whole series there we 24 cases in which analgesia was only fair or poor, on 4 of these failures occurred in the 105 "other procedures.

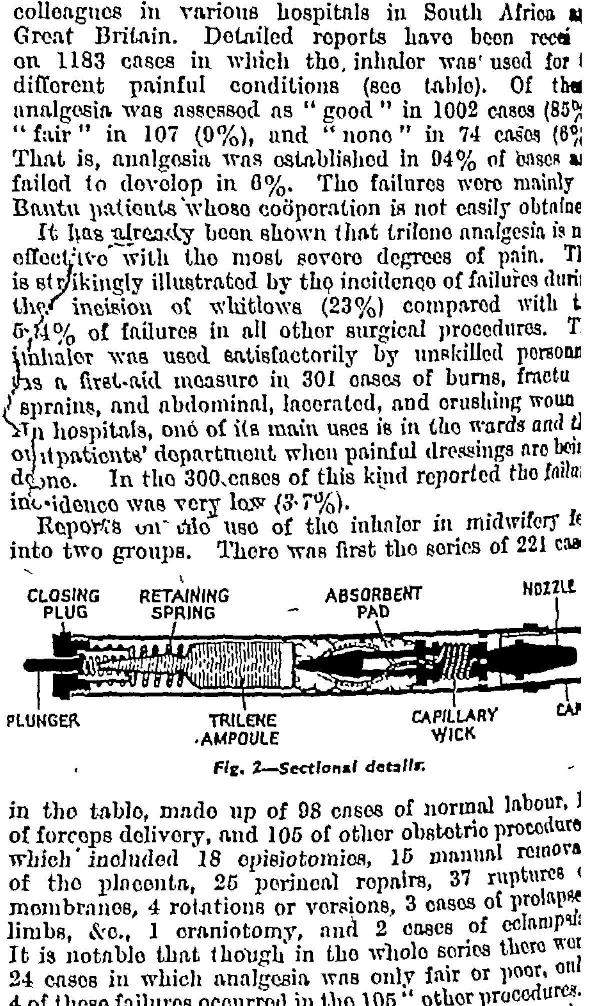

Fig. 2—Sectional details.

The second series comprised 450 cases, 300 *obtain* from a busy private practice and 150 from a native an Indian hospital where it was not possible to keep detailed records as in the first series. The results we assessed as follows:

European: Analgesia excellent .. .. 75% } 90%
,, satisfactory.. .. 15%
,, poor or none .. 10%

Native: Analgesia excellent .. .. 66% } 81%
,, satisfactory .. 15%
,, poor or none .. 19%

These results closely resemble those in the smalle series.

DISCUSSION

The efficiency of this inhaler is of the same order a the other machines available for self-administration o

Scher's (1946) figures for his 521 cases are good, 7% fair, and 9% none. Barratt and Platts obtained successful results in 85% of their cases, also noted a high failure-rate in opening whitlows; success-rate in midwifery was 86·5%. Hill (1944) duced satisfactory analgesia in 87% of his 62 patients. le Ellingham (1944), using Hill's machine for dentistry, rather more successful with 5 failures in 100 cases.

It appears, then, that whichever machine is used, in 100 cases trilene can be expected to produce a pletely successful analgesia, often with amnesia, in cases, partially to alleviate the pain in a further 9 or and to fail completely in the remaining 5 or 6 cases.

The inhaler described here does possess some advantages over the other machines, apart from the results obtained.

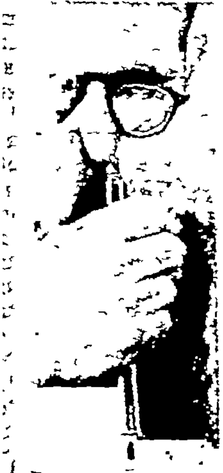

Fig. 3—Inhaler in use.

Its small size ($8^1/_4 \times {}^7/_8$ in.) and lightness (weight when fully loaded 10 oz.) allow it to be easily carried in the pocket, in a corner of one's bag, or in a first-aid kit. In contrast to other machines, it is virtually unbreakable. When fully charged, the spring holds the ampoule rigidly in place, and this can only be broken by striking the plunger firmly. Provided this is not done, the charged inhaler will withstand any amount of rough handling.

Once the inhaler is charged with an ampoule it is always *ready for use,* and provided that the ampoule is unbroken the inhaler may be left unused indefinitely but is ready when required. This is of particular importance when it forms part of a first-aid kit. If the inhaler is used only rarely a new charge should always be inserted after use. If it is used frequently this is not so necessary provided one remembers that the life of a single charge is 60–90 minutes of active use. The cap should always be replaced after use, and if this is done a partially expended charge will remain soaked in the absorbent pad.

The inhaler is used in a similar way to the familiar nasal inhalers, and, if the patient is told this, it will be correctly used at once. It can be issued as part of a first-aid kit in mines, ambulances, factories, &c., with the simplest of printed instructions. Anæsthesia cannot, of course, be self-induced with the inhaler.

The 6 ml. ampoule of trilene has itself several advantages over the larger bottle from which other machines are filled. It prevents waste, provides a constant charge which will produce analgesia for a known period, prevents loss by evaporation, and obviates any risk of deterioration. The ampoule is robust; when in the inhaler it has been flown at a height of 10,000 ft. and tested in the laboratory at a pressure equivalent to a height of 27,000 ft. without damage.

SUMMARY

A simple, compact, unbreakable instrument is described for the self-administration of trilene. It is designed to induce analgesia only and to be operated on the simplest printed instructions. It cannot self-induce anæsthesia and is therefore suitable for use by unskilled personnel in mines, ambulances, factories, and first-aid parties in general. It is equally suitable for use in planned minor surgery, dentistry, midwifery, &c.

It has been tested by 37 of my colleagues in 1183 cases comprising 67 different painful conditions. Analgesia was "good" in 85% of cases, "fair" in 9%, and in 6% failed to develop at all. This efficiency is equal to that attained with larger and more complex machines.

I am indebted to Dr. C. Langton Hewer, senior anæsthetist to St. Bartholomew's Hospital, London, and to Imperial Chemical (Pharmaceuticals) Ltd. for much helpful advice in the early stages of the development of this instrument; to my many colleagues who have been responsible for its clinical trials; to Mr. C. Whysall for the photographs; and to Dr. J. C. Thomas, senior pathologist, Natal Provincial Administration, for help in preparing this paper.

HOLT'S DIPHTHERIA TOXOID (P.T.A.P.)

Al PO₄ CONTENT, PURITY, AGEING, AND DURABILITY OF IMMUNITY

GUY BOUSFIELD
M.D. Lond.
With a note by L. B. HOLT, M.SC.

PRELIMINARY investigations showing the importance of using enough aluminium phosphate in the preparation of Holt's purified toxoid, aluminium-phosphate precipitated (P.T.A.P.), were reported previously,[1] when it was indicated that other work on the same lines would be undertaken.

Two further sets of P.T.A.P. samples, with different mineral carrier contents, prepared by Mr. L. B. Holt, were investigated under the same conditions as previously described—i.e., on Schick-positive children aged 1 year, partly in the same localities. In all cases single intramuscular injections of 0·5 ml. of P.T.A.P. were given, the Lf dosage of toxoid being kept constant at 5 units. The only variable factor in the different bottles was the concentration of aluminium phosphate. The effects of these single injections were studied by means of post-Schick tests 28 days later.

The first set of samples in this new series of observations were prepared from a relatively impure toxoid, batch E.2875, containing 10 Lf units per ml. and Al PO_4 in amounts of 3, 5, 7, 9, 11, 13, and 15 mg. per ml. The work was started when the samples were freshly prepared, but there were three bottles of each Al PO_4 concentration, a fact which will later be shown to have yielded some useful information.

TABLE I—SCHICK-CONVERSION RATES YIELDED IN 586 CHILDREN AGED 1 YEAR BY RELATIVELY IMPURE TOXOID, BATCH E.2875. DOSE 0·5 ML. CONTAINING 5 LF UNITS OF TOXOID (60% PURE IN TERMS OF PROTEIN)

Sample	Dose of Al PO_4 (mg.)	Post-Schick results		Conversion-rate (%)
		Positive	Negative	
H3	1·5	10	69	87·3
H5	2·5	4	79	95·2
H7	3·5	6	76	92·7
H9	4·5	5	80	94·1
H11	5·5	6	79	92·9
H13	6·5	3	81	96·4
H15	7·5	2	86	97·7

The results obtained from using all three bottles of each Al PO_4 concentration are given in table I. It appears that the differences in the amounts of Al PO_4 in the seven samples were too small to produce a clear-cut curve, but the results given by the extremes H3 and H15 seem to indicate the advantage of using an adequate amount of $Al\,PO_4$.

---

[1] Bousfield, G. *Lancet*, 1947, i, 286.

When these results are compared with curves constructed from work previously reported (see figure), the differences are seen to be not nearly so striking in the recent work. This may be due to the fact that the samples of P.T.A.P. used in the original work were slightly more purified than in the series quoted in table I. It is more likely, however, that the phenomenon is due to the fact that, in the more recent work, some of the subjects were London infants, who may have had a trace of basal immunity.

TABLE II—EFFECT OF AGEING ON P.T.A.P.

Sample	Dose of $Al\,PO_4$ (mg.)	Failure to convert to Schick-negative (%)	
		Bottle 1	Bottles 2 and 3
H3	1·5	14·0	10·5
H5	2·5	0·0	0·0
H7	3·5	10·0	5·6
H9	4·5	10·6	0·0
H11	5·5	11·0	2·7
H13	6·5	2·3	5·0
H15	7·5	2·2	2·2
Average for all samples ..		5·4	3·7

In the course of obtaining the results shown in table I, when I came to test children treated with the second and third bottles of each $Al\,PO_4$ concentration, it seemed that results were improving. There did not appear to have been any local changes in the prevalence of diphtheria infection to afford a degree of basal immunity to children treated with the second and third bottles. Accordingly the findings after the use of the first bottles of each $Al\,PO_4$ strength were analysed and compared with the joint findings after the use of the second and third bottles. All samples had been stored at room temperature, not in a refrigerator; this procedure was adopted deliberately, and the results (table II) appear to be significant, for bottles 2 and 3 had been subjected to several weeks of ageing under conditions which were anything but those supposed to be ideal.

Apart from group H13 (in which one or two refractory cases were possibly encountered in the use of bottles 2 and 3), there seems to be considerable evidence that better results are obtainable from samples of P.T.A.P. which have been stored for some weeks before use; and that the prophylactic improves even when stored at room temperatures. The fact also seems to emerge that if it is desired to use freshly prepared P.T.A.P. (see table II, bottle 1), the choice of $Al\,PO_4$ concentration should be about 13–15 mg. per ml. Larger amounts of mineral carrier than this cannot conveniently be used, though there is no reason to suppose that they would lead to excessive local reactions. Complaints of such reactions after intramuscular injection of P.T.A.P. have been entirely lacking, even with samples H13 and H15. No sterile abscess has been encountered, and one is forced to the view that the severe reactions which follow the injection of some batches of alum-precipitated toxoid (A.P.T.) are due to impurities brought down in the process of aluminium hydroxide precipitation.

The next investigation was made on batch E.3028, a toxoid of great purity. It was no less than 93% pure in terms of protein. This batch was also used shortly after preparation and no special precautions were taken about storage, as it was desired to find out whether the antigen retained its properties in spite of relative mal treatment. The results (table III) provide the answer t that point.

Each ml. of the samples contained 10 Lf units of toxoi plus amounts of $Al\,PO_4$ of 3, 5, 7, 10, and 15 mg. in th various preparations. The technique used was identica with that used in the children cited in table I. Th figures obtained are surprisingly good in comparison wit those of my original investigations (see figure, A). Th excellent performance of this very pure batch as com pared with series A (see figure) may be due to the fact tha here again some of the subjects were London childre Although all of them were originally Schick-positiv some may have had traces of basal immunity. Conside ing the figure as a whole, it will be noted that the critic part of the curves tends to be during the phase whe the smaller amounts of $Al\,PO_4$ are injected. Whe 5 mg. or more is injected, there is very little varia between the three curves. I regard this as an indicatio for the usage of adequate $Al\,PO_4$ in all preparation of P.T.A.P.

The results shown in table III are plotted as the cur C *in the accompanying figure, and it will be noted th* both curves B and C show a slightly better conversio rate when the mineral carrier is injected in amounts 7·5 mg.

It may well be asked: "Why all this fuss to try t obtain a few extra Schick-negative children in ever hundred as a result of a single injection of prophylactic?" The answer is that the few cases per cent. which do no become Schick-negative easily include the children wh are probably at the greatest risk if not proper immunised. It is child's play to protect about 90 *of children; but it is the last 10%* or so of relativel refractory subjects for whose sake it is necessary t *develop the very best prophylactics that we can discover* In some people the mechanism of antitoxin productio seems to be inferior or sluggish, and any immunit which they do develop appears to be relatively short lived. I have observed this repeatedly in the course o much long-range post-Schick testing.

The paramount importance of an efficient primar stimulus is too well recognised to need discussion here but it does follow that the more powerful and effectiv the *primary stimulus the better* will be the chance of permanent basal immunity being produced by a second inoculation. Thus, by using the very best prophylactics the odd 10% of *difficult cases may be* brought safely under the protection of the immunological umbrella.

TABLE III—SCHICK-CONVERSION RATES YIELDED IN 41 CHILDREN AGED 1 YEAR BY A PURE TOXOID (93% PURE IN TERMS OF PROTEIN)

Sample	Dose of $Al\,PO_4$ (mg.)	Post-Schick results		Conversion-rate (%)
		Positive	Negative	
K3	1·5	8	75	90·0
K5	2·5	7	80	92·0
K7	3·5	6	74	92·5
K10	5·0	7	70	91·9
K15	7·5	3	74	96·1

Many observations have been made on the results of using two injections of A.P.T. from various sources; but it is often overlooked *that only a really shockingly* bad sample will not produce a conversion-rate of about 95% as a result of two well-spaced injections. Samples not reaching this standard would be *found to put up* a truly woeful performance when the effect of a single injection was studied a month later, and the primary stimulus afforded must be poor indeed.

DURABILITY OF IMMUNITY PRODUCED BY P.T.A.P.

In the early stages of investigating the optimal Al PO_4 content of P.T.A.P., Schick-positive children aged 1 year were inoculated with a dose of the prophylactic containing only 3 Lf units in 0·3 ml. A similar 3 Lf dose was given a month later, and a post-Schick test was performed simultaneously. The amounts of Al PO_4 present in these 0·3 ml. doses varied from 0·15 to 1·2 mg. By taking the post-Schick tests at the same time as the second injections were given the long-range study of these cases is not upset by any additional stimulus such as would have been provided by a Schick test performed, say, 3 months after the second injection.

Of these cases, 57, which were all found to be negative as a result of a single 3 Lf dose a month after the injection but received a second 3 Lf dose at the same time as the post-Schick test, have presented themselves for long-range Schick tests two years after the original treatment. With one exception they gave a negative result.

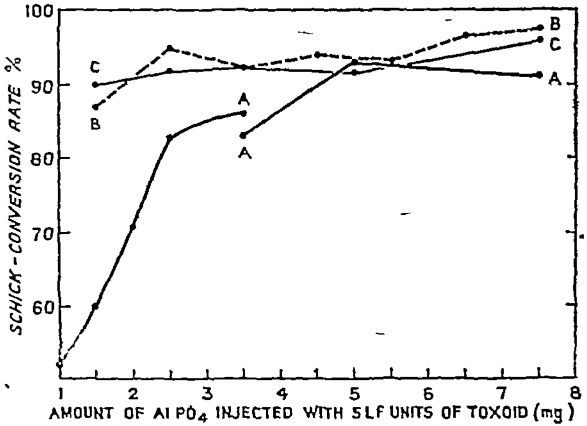
Further it has been possible to study a few cases which were Schick-positive a month after the first 3 Lf injection but had received another 3 Lf dose at the time this test was performed. These cases were all retested and found negative three months later. Of these children 47 had long-range tests two years later: 41 were Schick-negative still, and 6 had reverted to positive. All but one of the positive results in the long-range tests were in children who had been given P.T.A.P. with only smaller amounts of Al PO_4, which we now know to be inadequate for a really good prophylactic. Children given P.T.A.P. with the larger amounts of Al PO_4 have, with a single exception, maintained their immunity two years later after two 3 Lf doses of the prophylactic at a month's interval. These results can only be regarded as astoundingly good, even though the cases available for study are few; to realise just how efficient the antigen was, it is necessary to appreciate that these children received only the equivalent of 0·12 ml. of ordinary A.P.T. split into two doses. Including those inoculated with the less satisfactory prophylactic the 104 cases only show a relapse of 6·7% in two years despite the minute Lf dosage of the material used for inoculation.

TABLE IV—COMPARISON OF ORIGINAL SCHICK-CONVERSION RATES WITH PERMANENCE OF THE SCHICK-NEGATIVE STATE

Sample	Amount of Al PO_4 given in 0 3 ml. containing 3 Lf units of toxoid (mg.)	% of cases Schick-negative initially a month after 0·3 ml. dose	% remaining Schick-negative 2 yr. after 2nd 0 3 ml. dose
A	0 15	11	86 7
B	0 30	12	88 9
C	0 60	30	90·5
D	0 90	72	96 3
E	1·20	67	100 0

Relationship between Durability of Immunity and Original Schick-conversion Rate.—In the work just described five different concentrations of Al PO_4 were used in the various preparations. Results of the administration of these samples are set down in table IV to illustrate what I have long believed: that only antigens which yield a good initial conversion-rate can be expected to produce a durable immunity in most subjects.

The fact also emerges that adequate Al PO_4 must be included in all preparations of P.T.A.P. if it is desired to bestow lasting immunity, since the parent toxoid in the five samples in table IV was the same in each case. I cannot explain the original slightly lower conversion-rate given by sample E as compared with sample D except on the grounds of chance and insufficiency of cases to show the difference between two fairly good samples of prophylactic. Nevertheless the trend of the results is clear throughout the table.



Results obtained in children aged 1 year with different toxoids: A, relatively impure (63% pure) freshly prepared (results previously reported [1]); B, relatively impure (60% pure) freshly prepared (see table I); C, a toxoid of great purity (93% pure) freshly prepared. No. of children: A, 419; B, 586; C, 413. Curve A is broken because fresh material was prepared to cover the higher range.

SUMMARY

Holt's diphtheria toxoid, P.T.A.P., seems to exercise the most successful action as a primary stimulant when the amount of Al PO_4 injected with each dose is about 7·5 mg.

Judging from tables I and III, it seems clear that purification of toxoid by Holt's process does not damage the antigenic properties of the substances even when 93% purity in terms of protein is achieved.

It seems that P.T.A.P. will stand a considerable amount of casual treatment, without suffering any notable antigenic deterioration. The value of this from the practical standpoint needs no emphasis.

Long-range Schick tests have shown that the immunity conferred by only minute doses of P.T.A.P. is well maintained at the end of two years; with normal doses of 15 Lf units, instead of 3 Lf as used in the above work, it seems probable that the antigen will give a very high degree of permanent basal immunity.

Prophylactics which yield the best results from the primary stimulus may be expected to produce good durability of immunity, and the converse appears to be equally true. Further, the durability of immunity is bound up with the use of a prophylactic containing an adequate amount of mineral carrier.

My thanks are due to Dr. A. Anderson, M.O.H., Heston and Isleworth, Dr. H. W. Barnes, M.O.H., Camberwell, and Dr. P. L. T. Bennett, M.O.H., Fulham, for many facilities in connexion with the work reported here.

Additional Note

L. B. HOLT*

The following comments arise from Dr. Bousfield's clinical findings reported above.

Laboratory experiments, using guineapigs, have shown that there was no significant antigenic difference in samples of P.T.A.P. which were of the same age, and the same Al PO_4 and toxoid contents, but in which the protein purity of the toxoid was varied between the limits of 25 to 95%.

P.T.A.P. is prepared with the purest toxoid which can be obtained with reasonable economic yield, and is of the order of 1700 Lf/mg. protein nitrogen—i.e., about 75% pure. Eventually it is hoped to develop methods whereby it will be possible to use toxoid at least 95% pure for general issue.

---

* From the Wright-Fleming Institute of Microbiology, St. Mary's Hospital, London, W.2.

A major object behind this effort to obtain very highly purified toxoid is to be able to prepare a diphtheria prophylactic of very high antigenicity, and one employing the absolute minimum amount of diphtherial protein, in order that subjects of all ages may readily be immunised with the minimum of reaction in hypersensitive individuals.

It has been found by experiments on guineapigs that P.T.A.P. increases in antigenic potency on storage.

In regard to storage, the Therapeutic Substances Act lays it down that the date of manufacture shall be stated on the label of each package of diphtheria prophylactic but it defines the date of manufacture as the date when the product is released from cold storage (with a time-limit from the date of actual preparation). The date of manufacture which appears on the label of the bottle of P.T.A.P. is that on which it is removed from the refrigerator after having been matured for at least six months.

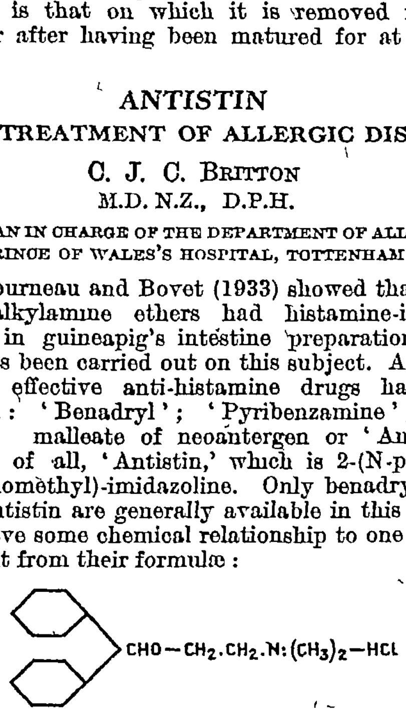
ANTISTIN

IN THE TREATMENT OF ALLERGIC DISEASES

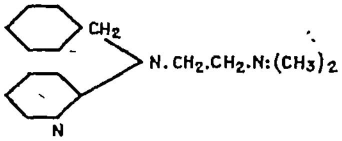
C. J. C. BRITTON
M.D. N.Z., D.P.H.

PHYSICIAN IN CHARGE OF THE DEPARTMENT OF ALLERGY,
PRINCE OF WALES'S HOSPITAL, TOTTENHAM

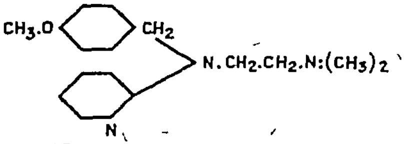
SINCE Fourneau and Bovet (1933) showed that certain phenolic alkylamine ethers had histamine-inhibiting properties in guineapig's intestine preparations, much research has been carried out on this subject. At present some five effective anti-histamine drugs have been synthesised: 'Benadryl'; 'Pyribenzamine'; 'Neo-antergan'; malleate of neoantergen or 'Anthisan'; and, latest of all, 'Antistin,' which is 2-(N-phenyl-N-benzylaminomethyl)-imidazoline. Only benadryl, anthisan, and antistin are generally available in this country. They all have some chemical relationship to one another, as is evident from their formulæ:



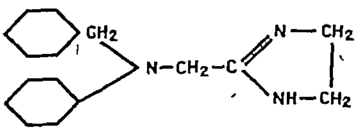
Benadryl



Pyribenzamine



Neoantergan



Antistin

They all have a similar anti-histamine action as shown by their protective value in the prevention of anaphylactic shock in animals. Unfortunately all of them cause various unpleasant side reactions which limit their use in certain patients. These side reactions vary from patient to patient and with the different drugs. Thus some patients may suffer severe side reactions from, say, benadryl but none from antistin, and vice versa.

RESULTS OF TREATMENT OF ALLERGIC CONDITIONS WITH ANTISTIN

Condition	No. of cases	Great benefit	Moderate benefit	No benefit	Reactions
Hay-fever	30	15	7	8	12
Urticaria	11	3	2	6	4
Vasomotor rhinitis .	10	3	5	2	4
Pruritus ani	1	1	—	—	—
Allergic conjunctivitis	1	1	—	—	—
Migraine	1	1	—	—	—

Two papers have been published on the use of antistin in allergic conditions. Bourquin (1946) found it of value in allergic conjunctivitis, and Schindler (1946) obtained good results in many of 39 cases of urticaria, pruritus, and asthma. Pharmacological details were published by Meier and Bucher (1946).

Of my own series of 85 cases treated with antistin only 54 could be adequately followed up and had a complete course of treatment. Of the 54 patients 30 had seasonal hay-fever (pollinosis), 11 urticaria or angio-neurotic œdema, 10 vasomotor rhinitis, 1 pruritus ani, 1 allergic conjunctivitis, and 1 migraine. No cases of asthma other than hay-asthma are included in this study, since my experience of anti-histamine drugs in this disease has not been so favourable as with the more usual antispasmodic drugs, and indeed some cases have been made much worse. Some of the patients with hay-fever also had hay-asthma. This type appears to react more favourably to these drugs, and the asthma appeared to improve in parallel with the hay-fever when it was benefited.

The dosage prescribed in each case was one tablet (0·1 g.) given at night before going to bed and again in the morning before rising. If these caused no unpleasant reactions, the dose was doubled and then increased gradually, if symptoms of the condition still persisted, until relief was obtained or until a maximum of two tablets four times a day was reached. In all 50–60 tablets were given. If relief was not obtained within this limit, the drug was considered valueless.

The table shows that antistin was of benefit in 38 (70%) out of 54 cases. In all cases the condition relapsed at once on stopping the treatment.

Side Reactions.—In 20 (37%) of the 54 cases there was some type of unpleasant side reaction, and in 7 of these it was so severe that treatment with antistin had to be abandoned. The reactions came on at any dosage; but, though they were more common with the larger doses, a fairly severe reaction might develop *with the first dose.* The *types* of reactions in order of frequency were as follows:

Nausea . ..	9	Coughing attacks	2
Drowsiness .	4	Disorientation	1
Faintness . ..	3	Depression and fever	1
Giddiness	3	Diarrhœa ..	1
Headache	2		

DISCUSSION

Antistin is an effective anti-histamine drug in many allergic conditions. Like the other anti-histamine drugs it does not cure; so desensitisation remains the only method for clinical cure in most cases of extrinsic allergy.

The place for anti-histamine drugs is during the period of investigation and until the desensitisation has reached a sufficient level to limit the symptoms. In many cases of intrinsic allergy, or where the offending allergen cannot be discovered, these drugs are invaluable.

The severity of the side reactions in some cases indicates the imperative need for beginning with a small dose and increasing it slowly. This fact must be emphasised, since deaths have been reported following the use of anti-histamine drugs. In these cases it appears that the patient was not sufficiently warned of the possible side effects and had taken a high dosage from the beginning. The side reactions to antistin appear usually to be of a type which are less troublesome than the disorientation and severe drowsiness commonly found with some other members *of this group, but all the anti-histamine drugs* are safe if the initial dosage is kept low and the patient is warned. I have found that antistin can be used with good effect in cases where benadryl or other drugs of this group have failed or have caused severe side reactions. Conversely, excellent results may sometimes be obtained with the other anti-histamine drugs when antistin has failed.

SUMMARY

In 37 of 54 cases of hay-fever, urticaria, vasomotor rhinitis, and other allergic conditions, antistin gave much relief.

Side reactions developed in 20 of the 54 cases, but only in 7 were they so severe that the antistin had to be stopped.

With all anti-histamine drugs, the patient should be warned of the possibility of side reactions. The initial dose should be kept small and the dosage increased slowly. The first dose and any increases should be given at a time when the patient will not be called on to perform skilled movements depending on acts of judgment—e.g., driving a motor-car.

I am indebted to Ciba Laboratories Ltd., Horsham, for supplies of antistin.

Preliminary Communication

PARA-AMINOSALICYLIC ACID IN TUBERCULOSIS

EARLY RESULTS OF CLINICAL TRIALS

AMONG a series of benzoic- and salicylic-acid derivatives investigated by Lehmann [1] in Sweden, *para*-aminosalicylic acid (P.A.S.) was found to have the most active bacteriostatic *action on the tubercle bacillus and to be relatively* non-toxic to animals (except guineapigs). It was then used in human tuberculosis in Sweden by Vallentin,[2] in whose opinion the results were "fairly promising."

A new method of synthesising this compound was evolved by Mr. D. E. Seymour (director of research, Herts Pharmaceuticals Ltd.) in 1946, and, after further toxicity tests in animals, a sufficient quantity of P.A.S. became available for clinical trials to be started at the Grove Park Hospital in March, 1947.

To maintain a blood-level of at least 10 mg. per 100 ml. it was estimated provisionally that each case treated by mouth would require 80–140 g. of P.A.S. every week (we still consider this dosage advisable for parenchymatous lesions), but owing to unavoidable manufacturing difficulties continuity of treatment in such dosage has not always been possible. It was found, however, that small quantities of P.A.S. (1·5–3·0 g. weekly, as a 10% solution in sterile distilled water) had an effect on empyemata, &c., when applied locally to the pleural space; hence 9 cases have received the drug in this way alone. Two intrathecal injections, each of 0·5 g. in a 5% aqueous solution, were given, together with oral dosage, in our single case of tuberculous meningitis complicating extensive pulmonary disease. No undue disturbance was noted by such methods of medication, except that high dosage of the acid itself given by mouth produced nausea and vomiting; but this effect has been slight since we have substituted the sodium salt.

Up to date, 19 patients in the hospital have received P.A.S. All of these patients have pulmonary tuberculosis but only 6 were given the drug as treatment for their pulmonary lesions; thus these 6 cases will be referred to as the "pulmonary series."

PULMONARY SERIES

We tried to choose cases demonstrating infiltration without cavity, single cavity *with little infiltration*, pneumonic, miliary, or fibrotic lesions, but no case was chosen for P.A.S. treatment unless we had evidence that the disease was active (sputum-positive) and progressive during an observation period of at least two months immediately preceding the start of the drug.

No definite conclusions can be drawn from this small series, but the drug does seem to have had a beneficial effect. Within a few days of the first dose the temperature and erythrocyte-sedimentation rate (E.S.R.) fell sharply, and this improvement was maintained unless the treatment was interrupted, when both temperature *and E.S.R. rose towards their former level until a further* course was given, when they again fell immediately; these falls in temperature were not attended by sweating. More slowly—i.e., over a few weeks—there was a fall in the pulse-rate and an increase in weight, vital capacity, and hæmoglobin content of the blood. The quantity of sputum rapidly decreased in each case, with a striking reduction in the number of tubercle bacilli present. The morphology of the bacilli also changed; beading and striation were noted, and acid-fast granules appeared which persisted for a considerable time after ordinary bacilli had disappeared (for record purposes such sputum was still regarded as "positive"). These responses to treatment were accompanied by improvement in the general condition and in the radiological appearances; particularly striking was the reduction in size of some pulmonary cavities during medication.

COMPLICATING LESIONS

Renal Tuberculosis.—One woman was treated with P.A.S. by mouth for tuberculosis of the upper pole of her left kidney, confirmed by retrograde pyelography and by finding albumin, pus, blood, and tubercle bacilli in the urine. From the 12th day onwards no further tubercle bacilli appeared in the urine, but pus, blood, and albumin persisted until the 11th week when the urine finally became clear. She has had no recurrence of renal signs or symptoms up to date—i.e., six months afterwards.

Meningitis.—Our one case of tuberculous meningitis complicating pulmonary tuberculosis (the diagnosis was established by lumbar puncture and confirmed by autopsy) was treated by mouth and with two intrathecal injections. His meningitic symptoms became virtually negligible within twelve hours of the commencement of P.A.S. and remained so throughout treatment, while we thought that his life was slightly prolonged by this medication, particularly as he died within thirty-six hours of its cessation.

Enteritis.—Recently one patient, with miliary spread and deteriorating rapidly, developed tuberculous enteritis;

[2] Vallentin, G. *Svenska Läkartidn.* 1946, 43, 2047.

no great improvement has been achieved so far in her general condition, but the first fortnight's administration of P.A.S. by mouth has reduced the frequent diarrhœa to one semi-solid stool daily, besides alleviating the pain.

Monaldi Drainage.—One patient, being treated by Monaldi drainage for a large apical cavity, had P.A.S. mucilage instilled daily direct into this cavity and left for eight to twelve hours without suction; the discharge was appreciably diminished, but nothing further can yet be claimed for the case.

Empyemata, &c.—Of 9 patients treated by local instillation of P.A.S. into the pleural cavity for tuberculous empyemata, 3 had open sinuses in the chest wall, another had a bronchopleural fistula in addition to a sinus, and 1 had a bronchopleural fistula but no sinus. The results obtained in these cases have been particularly rapid and striking.

The first patient in whom this method was tried had a chronic tuberculous empyema with a bronchopleural fistula; open drainage had been employed for two years before thoracoplasty and the fistula, sinus, and empyema cavity had then remained open for ten months. A 5% suspension of the pure acid in water was inserted into the empyema cavity which was then sealed for three days, and this treatment was repeated a fortnight later. Within a month of the original injection of P.A.S. the chest-wall sinus had healed, the patient's symptoms of bronchopleural fistula had gone, and by X-ray examination the pre-existing empyema cavity could no longer be seen, nor could pus be detected by needling. Without further treatment this man has worked at his former occupation for the last four months and his recent film shows no sign of relapse.

In another man multiple sinuses have healed, and there is evidence of commencing healing in 2 further similar cases. In the remainder the empyemata have either been obliterated or (in the later cases) are showing a definite tendency towards this end; in the latest bronchopleural fistula the lung is re-expanding, though the fistula remains patent, and spread in the contralateral lung has been checked. In these empyemata, radiological examination suggests a deviation from the usual mechanism of re-expansion, and a proliferation of deposit (probably fibrinous) on the parietal pleura.

In the ordinary way we would have expected at least 3 of this group to have needed a thoracoplasty for the obliteration of the empyema space, but this operation would probably have been postponed because of multiple sinuses, emphysema, contralateral disease, &c.; time saved for the patient must also be taken into account in assessing the value of the drug. Further, even with the small dosage employed, the beneficial effects of P.A.S. on the empyema, &c., have in most cases been accompanied by improvement in the pulmonary lesions; as yet no patient in this series has shown symptoms of retrogression since P.A.S. was begun as a "local application."

CONCLUSION

Time alone can determine the stability of the results so far achieved with P.A.S. But we feel justified in recording the beneficial effects noted in these patients with various tuberculous lesions, and in suggesting that the improvement has seemed to be more rapid than with previous methods of treatment.

We wish to thank Herts Pharmaceuticals Ltd. for the *para*-aminosalicylic acid, and its sodium salt, used in these preliminary trials.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Carcinoma of the Breast

AT a meeting of the section of surgery on Dec. 3, with Sir MAX PAGE, the president, in the chair, a discussion on the treatment of carcinoma of the breast was opened by Sir GORDON GORDON-TAYLOR. Tracing the evolution of treatment, he paid special tribute to pioneer workers at Middlesex Hospital, including Charles Moore, Sir Alfred Pearce Gould, and W. Sampson Handley. Sir Gordon's own surgery of mammary cancer has been largely modelled on that of Handley; but he has not followed Handley in the employment of radium at the time of operation or in the use of postoperative radiation. On over a dozen occasions he has deliberately removed the chain of anterior mediastinal glands along with the internal mammary vessels after resection of the 2nd and 3rd costal cartilages; in retrospect he regrets that he has not more often performed this manœuvre.

Confidence in preoperative and postoperative irradiation must tend to curtail the extent of surgical ablation. In 1938 four different procedures prevailed among 7 surgeons throughout Britain: (1) 25% undertook radical operation without irradiation; (2) 44% employed irradiation as a supplement to radical operation; (3) 29% used irradiation after radical operation in group 2 cases only; and (4) 2% favoured irradiation with or without a local operation. Since 1938 the exigencies of war have thrust much of the treatment on to radiotherapeutic clinics. Sir Gordon eschews postoperative radiation for cases in groups 1 and 2; "For such I have preferred a sharp knife, a stout heart, and unquenchable optimism." He was emphatic, however, that when the condition has advanced beyond stage 2, and for treatment of supraclavicular glands and bone metastases, radiation is the method of choice. Even among those who advocate routine ancillary radiotherapy there is no unanimity as to indications or method. Stuart Harrington found that, whether there was axillary-gland involvement or not, there was no appreciable difference in the 10-year survival-rate between those receiving radiotherapy and those who did not receive it. Truscott concluded that between 1926 and 1935 treatment was best when surgery alone was employed, and that from 1935 onwards the evidence was insufficient to say whether the combination of radiotherapy with surgery is better than surgery alone.

Few papers dealing with radiation refer to the morbidity from this treatment. Apart from unhappy local effects, sickness and other untoward sequelæ may lower resistance to any malignant cells remaining after operation. Recurrence has taken place as long as 32 years after operation; in some no causal factor, except perhaps age, can be impugned as fostering the recrudescence; but in others recurrence appears to have been preceded by intercurrent disease or by surgical operation for some independent condition. Sir Gordon has seen a recurrence in the scar 17 years after a radical mastectomy and a few weeks after a severe attack of acute pyelonephritis; he has also seen recurrence in the scar follow an operation for hæmorrhoids performed 16 years after the initial amputation. In three cases recurrence manifested itself shortly after a gall-stone operation, while in another patient recurrence seemed to be related to a herniorrhaphy performed under local anæsthesia. "Cancer immunity," after being broken down, seems sometimes to be restored, and Sir Gordon has seen patients survive recurrence for as long as 10 years. The vagaries of this "immunity" or "resistance" are seen in alternating efflorescence and retrogression or disappearance of cutaneous nodules and even of invaded lymph-glands: while preternaturally slow growth of a mammary tumour and the protracted absence of metastases are indicative of the same cancer resistance. Still more amazing is the disappearance of a cancerous mammary growth and its secondaries.

Investigation has shown that the average natural duration of untreated cases of mammary cancer is about 3½ years. Treatment should, therefore, be gauged by the

0-year survival-rate. Of his total of 644 cases of primary ncer of the breast submitted to radical operation, 33 were treated up to June. 1928; and among these e 10-year survival-rate was: group 1, 84·07 %; group 2, 4 %; group 3, 6·5 %. Almost without exception the nclusions of the surgeon-radiotherapist "combines" e based on 5-year survival-rates;" when their figures 10 years convincingly surpass those which I have en from radical surgery alone, I may then be preed to solicit the routine aid of radiotherapy for the oup 1 and group 2 patients."

RADIOTHERAPY

Dr. ROBERT MCWHIRTER discussed the 5-year llow-up of 2809 cases referred to the Royal Infirmary, dinburgh, between 1930 and 1945. In 364 operable cases tages 1, 2, and 3, Manchester classification) treated etween 1930 and 1934 by radical operation alone, the mber developing recurrences in the chest wall, axilla, d supraclavicular region of the affected side was almost 0% within 5 years of operation: in this proportion the peration was doomed to failure because the disease was t eradicated locally.

This observation led, in 1935, to the adoption of stoperative radiotherapy, as a result of which the rcentage of local recurrences within 5 years was duced from 40 to 14; and the 5-year survival-rate as raised from 37 % to 51 % in the treated cases.

The trauma of the operation and the opening up of ssue planes, especially in the axilla where an "en-bloc" ssection is difficult to perform and where many lymhatic trunks must be cut across, suggest that malignant lls may be disseminated before X-ray therapy can be pplied. In an attempt to overcome this difficulty ses have been treated since 1941 with simple mastecomy followed by postoperative radiotherapy. Cells ay still be liberated when a simple mastectomy is rformed, but these are unlikely to pass the intact arrier of the axillary drainage system; and by not issecting the axilla the risk of dissemination from he axilla at operation is eliminated. Moreover, the verage interval before X-ray therapy is started is horter after simple mastectomy than after the radical peration. Keynes has achieved good results by a ethod which is essentially the same except that he used adium implantation.

Dr. McWhirter underlined the importance, in assessing he value of treatments, of relating results not simply o the cases actually treated but to the number of cases o which the method can be applied. A true comparison an be obtained only by expressing the number of urvivors from each method as a percentage of the total ases referred, irrespective of the treatment used. By hese standards the 5-year survival-rate of all operable ases treated by radical surgery is 35 %, and of all cases, perable and inoperable, 20–25 %. Moreover, he said, his gures refer to a large general hospital and include many dvanced cases.

The following 5-year survival periods have been btained in operable cases: 1930–34 (radical surgery nly) 35·6 %; 1935–40 (radical surgery and postoperaive radiotherapy) 44 %; 1941–45 (simple mastectomy nd postoperative radiotherapy) 56·0 %. This gives tatistical support to the belief that by not dissecting the xilla the risk of disseminating cells is reduced. Conirmation is forthcoming from the results in inoperable ases, though it was not possible or advisable to treat all f these by the methods adopted for each period. In 1930–34 no inoperable case survived 5 years; in 1935–40 only 2·5 % survived for this period, which uggested that postoperative radiotherapy was rendered ineffective by dissemination of cells at the time of operation: lastly, in the period 1941–45 the 5-year urvival-rate was 14·1 %—or, if the localised inoperable cases are taken alone, 24·6 %.

Analysis of all cases referred to the Royal Infirmary in the 1935–40 period shows that among a total of 790 operable and inoperable cases the 5-year survival-rate was 32·4 %; and among 1345 cases in 1941–45 the rate was 43·2 %. When the cases with evidence of distant metastases are excluded, the 5-year survival-rate for 1941–45 is 50·1 %; and this figure is the more remarkable when it is borne in mind that not all cases, even in the operable group, were treated by simple mastectomy and radiotherapy.

At the Royal Infirmary the technique of simple mastectomy and postoperative radiotherapy is being continued, with the addition of X-ray therapy to the ovaries in women over the age of 35 with a view to influencing distant metastases.

Dr. McWhirter concluded with the following points in procedure: (1) preoperative preparation by iodine is contra-indicated; (2) the skin incision should be as short as possible; (3) tension on skin flaps may delay healing and the application of radiotherapy; (4) where the primary tumour is mobile on the pectoral fascia, the fascia should not be removed; (5) if there are no palpable axillary glands no dissection should be performed, but superficial mobile glands in the subpectoral region may be removed; (6) if the patient is very stout it is better to carry out a radical operation; (7) supraclavicular glands should never be removed; (8) adhesive should not be applied to the skin. In postoperative radiotherapy: (1) only one full course of X-ray treatment should be given; (2) X-ray treatment should be begun as soon as possible after operation—usually 2 weeks after; (3) the chest wall must be treated by tangential or glancing fields to avoid lung fibrosis; (4) an adequate dosage must be given; (5) the above method should not be used with an apparatus of lower voltage than 250 kilovolts since an adequate depth dose cannot be delivered to the axilla.

ASSESSMENT OF RESULTS

Sir STANFORD CADE said that the peak incidence of cancer of the breast is in the 55–60 age-group; and he therefore chose 55 years as the age at which to consider expectation of life in connexion with the disease. The breast is the least rapidly lethal of all sites of cancer —a consideration which should affect the choice of treatment. The mean duration of life in untreated cases is 39·3 months. Major Greenwood found actuarially that for a women of 55 the normal expectation of life was 18·87 years; with untreated cancer of the breast it was 3·8 years; with cancer of the breast treated under average conditions it was 5·78 years; while with cancer treated under the best conditions it was 12·93 years. The qualifications "best" and "average" are determined by (1) the stage of the disease, and (2) the type of treatment; and these two factors are the key to an unbiased assessment of treatment methods. Of all factors affecting prognosis, stage of the disease is the most important; and the following classification was suggested:

Stage 1: Tumour of the breast only.

Stage 2: Tumour of the breast, plus skin changes and/or axillary glands.

Stage 3: Tumour of the breast, plus supraclavicular gland or contralateral axillary gland or fixation to pectoral fascia.

Stage 4. Skeletal or visceral metastasis.

The zone of demarcation between good and evil prognosis is the clinical state of the axillary glands. The treatment of choice for stage 1 cases is radical mastectomy; and postoperative radiation in this group is of very doubtful value. The operative mortality is very low; in over 11,000 cases operated on in British teaching hospitals the rate was only 1·65 %. In stage 2 operation alone offers a chance of 5 years' survival in only about 20–30 % of cases. This group comprises three types of skin invasion: (1) direct spread and fungation, which is the least malignant; (2) diffuse invasion with œdema, which is of grave significance; (3) invasion of the skin by discrete nodules, which is a death sentence. With the last two types of skin involvement incalculable harm is done by radical mastectomy. Here radiation is the weapon of choice, and it converts some cases to group 1.

Simple mastectomy is suitable to the aged, for the removal of a fungating mass, in bad surgical risks with localised disease, and in cases where radiation is not available or suitable; but as a routine surgical procedure simple mastectomy is a retrograde step and is quite unwarrantable. Radiation is of value: (1) as the sole treatment in stage 3 cases; (2) as a preoperative measure in stage 2 cases; and (3) as a postoperative measure, chiefly in stage 2 cases. Methods should not be allowed to deteriorate: "If women are to be mutilated by amputation of the breast, let them at least derive the maximum benefit from such mutilation."

INTERCOSTAL GLANDS

Mr. R. S. HANDLEY said that, in association with Dr. A. C. THACKRAY, he had been removing the 2nd space intercostal gland of the internal mammary chain from cases of mammary carcinoma, to discover the frequency with which the internal-mammary glands are invaded. The 2nd space was chosen because it contains the largest and most constant gland of the internal-mammary chain. In 20 cases so far examined in this way, glandular involvement was found as follows: no glands 6; axillary glands 3; intercostal glands 2; axillary and intercostal glands 9. No intercostal gland larger than an orange pip has been found; but invasion of the space is nearly always detectable by the matting of the tissues around the internal-mammary artery. It is difficult to believe that carcinoma cells lying almost on the pleura can be harmless. If the intercostal glands are invaded, the patient clearly cannot be cured by surgery alone; additional radiotherapy is needed, and it is doubtful if radical mastectomy is then indicated. Recently Mr. Handley has done two or three cases in which the first step was a 2nd intercostal-space biopsy; if from a frozen section it was found that the space was invaded, the operation was confined to simple mastectomy.

Reviews of Books

The Human Approach

A Book for Medical Students. HENRY YELLOWLEES, M.D., F.R.C.P., physician for mental diseases, St. Thomas's Hospital. London: J. & A. Churchill. 1946. Pp. 189. 10*s.* 6*d.*

MEDICAL students will find here a vigorous and frankly personal statement of what one experienced psychiatrist thinks should be their outlook on psychological medicine. The author appears as a man of strong likes and dislikes, with a gift for homily. He warns the student not to feel alarm or elation if some statement in the book seems somewhat inconsistent with a previous or later statement; and indeed the style is free of any dry-as-dust liking for impersonal precision. The book contains a lot of shrewd advice, sometimes amusing, sometimes provoking, and continuously lively. There can be no doubt that many students will be pleased to meet here a psychiatrist who has definite views which are useful in practical life, by no means abstruse or far-fetched, and expressed moreover in colourful simple language.

Hypnoanalysis

LEWIS R. WOLBERG, M.D., lecturer in psychiatry, New York Medical College. London: W. Heinemann. 1946. Pp. 342. 21*s.*

IN psychological treatment the notion of catharsis as the essential curative process has gained wide acceptance: it is easy to grasp, because of its physical and philosophical associations, and many psychiatrists are impressed by dramatic instances of its occasional efficacy. Freud and many of his followers have stressed the limitations of the cathartic method, but abreaction still figures largely in the reports by non-Freudian psychotherapists of how their patients—especially their war-time patients—were made well. Narco-analysis and hypno-analysis are methods employed to facilitate the conscious recall of the memory of painful events; but Dr. Wolberg makes it clear that this is not the sole or primary aim of his method, in which hypnotism is brought in as a technical device for making psycho-analysis smoother and quicker, because less obstructed by resistance on the patient's part. The ingenuity and resource of Dr. Wolberg in conducting the hypno-analysis of Johan R. (the gifted schizophrenic patient to a detailed account of whose treatment the first half of the book is devoted) is of such obvious value at every stage of the procedure that hypno-analysis emerges as yet another variety of psychotherapy whose success depends rather more on the talents of the practitioner than on the particular practice he adopts. Nevertheless hypno-analysis is a technique with many advantages, as Lindner, Erickson, and some others have shown, and it is wholly to be welcomed that such a promising development in psychological treatment should be put on record, in straightforward language, to enliven the current literature of individual psychotherapy, with its intricate polemics and reports of triumphs. In part 2 the rationale of the hypno-analytic technique is fully discussed, with illustrations drawn from Dr. Wolberg's experience of other subjects besides Johan R. Neither the explanations nor the claims are extravagant. There is also a reflective critical interpretation, by Dr. A. Kardiner, of the dynamics of the therapeutic process in Johan R. Altogether this book has the merits, especially to be prized in works on psychotherapy, of having something comprehensive, balanced, and fresh to say.

Old Age: its Compensations and Rewards

A. L. VISCHER, DR.MED. With a foreword by Lord AMULREE, F.R.C.P. London: Allen & Unwin. 1947. Pp. 200. 12*s.* 6*d.*

THIS translation of a remarkable book published in Basle in 1942 is overdue; but its appearance is happily timed with the final emancipation of the aged poor from the degradation of the workhouse (which Sidney Webb just lived to see). The old people's hostels adjoining the municipal hospital in Basle may well serve as a model for our health authorities, and Dr. Vischer might be able to find Mr. Bevan a name for them that carries no slur. The delay has perhaps had something to do with the attractive format of the book and with Bernard Miall's sensitive and accurate rendering of the author's style. This matters more since the subject matter is not so much geriatrics as the wider gerontology, and the translation should appeal to a wide circle of readers among the elderly, to many of whom the original brought consolation and encouragement. Doctors who have not time to digest Cowdry's massive collection of essays on the *Problems of Ageing* will find in Dr. Vischer's work the physiological and psychic questions stated, if not fully answered.

Occupational Diseases of the Skin

(2nd ed.) LOUIS SCHWARTZ, M.D., medical director, United States Public Health Service, chief of dermatoses section; LOUIS TULIPAN, M.D., clinical professor of dermatology and syphilology, New York University; SAMUEL M. PECK, M.D., dermatologist, Mount Sinai Hospital, New York City. London: H Kimpton. 1947. Pp. 964. 63*s.*

IDEALLY all pictures of skin lesions should be in colour, though no doubt this is expensive. The second edition of this good book has 140 black-and-white illustrations to only one colour plate, and some of the uncoloured photographs do not give accurate impressions of the lesions. The authors provide fascinating and sobering accounts of the risks to which workers' skins are subjected by various irritants, and discuss fully the treatment and prevention of occupational dermatitis. The occupational skin diseases of the medical and allied professions are not often so well described as they are here, and a glance at the photographs of radiodermatitis in a physician, formalin dermatitis in an anatomist and in a morgue-keeper, procaine dermatitis in a dentist, potassium mercuric iodide dermatitis in a nurse, and verruca necrogenica in a post-mortem attendant might well give pause to aspirants to these professions. Tested for information on specific subjects the book usually passes with honours. Thus the differential diagnosis of fungus infections of the skin from industrial dermatitis is given in satisfying detail. Compensation for industrial dermatitis is considered mainly from the American angle, though a brief reference is made to the position in Great Britain and elsewhere; in all other respects the book is as useful a reference book in this country as in the United States. Its value lies in the authors' extensive first-hand experience of occupational skin lesions as well as in their exhaustive reading of the contributions of other people and of other countries.

Bamford's Poisons: Their Isolation and Identification (2nd ed. London: J. & A. Churchill. 1947. Pp. 304. 21*s.*).—The second edition of this useful laboratory manual for chemists who have to deal with cases of poisoning has been prepared by Mr. C. P. Stewart, PH.D. He has followed the practice of Mr. H. F. Bamford, the original author, in describing methods which he knows, by personal experience, to be reliable, and—apart from adding some notes on the preparation of reagents—he has left the scheme for the identification of alkaloids.

Leading thoughts on **CHILBLAINS**

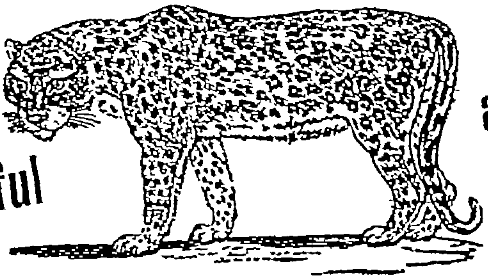
. . . remembering last winter's high incidence of chilblains not only among chronic cases but in many first sufferers . . . considering how best to protect chronic sufferers from the same cause and effect this winter

These thoughts lead to the effective *prophylactic* measure that Colloidal Calcium with 'Ostelin' provides. Three to five injections of this colloidal solution of calcium and vitamin D are normally sufficient to see the patient safely through the winter. If the tendency to chilblains persists, a further reinforcing course should rapidly restore the circulation in the skin capillaries to normal. *Injections are painless and the course is inexpensive*

COLLOIDAL CALCIUM with OSTELIN

0.5 mg colloidal calcium 5 000 I u vitamin D per cc.
1 cc. Ampoules in boxes of 6, 12 and 100 30 cc. bottles.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX BYRon 3434



ON THE LITHENESS of the leopard depends his safety; survival depends on adaptation to environment. Man, too, must adapt himself to modern conditions. Failure in 'adaptation' leads to certain functional deficiencies, the rational treatment for which may be the use of the natural sex hormones (steroids).

The B.D.H. range of sex hormones includes forms for all accepted methods of administration. Oestroform is preferred for all states of ovarian hypofunction. Detailed information is available on request.

THE BRITISH DRUG HOUSES LTD. LONDON N.1

Niceties of Social Work

THE general practitioner is daily faced with the resenting symptoms of social maladies which he has o time to study and treat. There is the girl complaing of constipation, who works in an office, lives in dgings, knows nobody, and takes no proper food r exercise; or the old man living alone, not ill, t beginning to find household chores too much r him; or the woman whose occupation has gone cause her children have married and left home, and he has formed no other interests; or the child with e mild behaviour disorder who looks like getting to trouble but has not yet done so Such people, Dr. BERYL HARDING [1] has suggested, could readily e helped by some friendly woman who knows the cial resources of the neighbourhood. Work of is kind, she argues, should not take up the time a highly trained person, whether health visitor or lmoner; and it might be done, she thinks, by part-me voluntary helpers under skilled supervision.

The problem is more complex than appears at rst sight; for social workers in various fields tell that though voluntary helpers sometimes work armoniously under trained staff—especially in areas here such an arrangement is traditional—the ommoner end is disharmony, either because the oluntary helper is over-confident and cannot accept udance, or because the trained worker is officious d overbearing. Nor can a new voluntary helper uckly learn precisely what resources are there to e tapped Our social services and amenities seem o have some congenital anomaly of coordination hich renders them ataxic, dysarthric, and full of ood-intention tremors. It may be that once they re supported by the spinal brace of the National ealth Service a few remedial exercises will work onders, but in the meantime no single person in n area seems to be fully informed of their scope: ertainly not the general practitioner, nor even, we re told, the medical officer of health. They are herefore exceedingly difficult for the lay newcomer o master. Even under the supervision of an almoner r a health visitor, a voluntary helper would not live p to her name until she had had several months' uided experience, and it is doubtful whether time an be spared by trained staff to teach her.

What other solutions present themselves? Who ust be responsible for ascertaining cases? It is the octor who often hears the story first. But for the ext ten years at least doctors are going to work arder than ever, and they are going to have less pportunity to deal with even the urgent problems, et alone the vague preliminaries of ill health. This s especially unfortunate at a time when students and ractitioners alike are beginning to have their minds more attuned to prevention But if we cannot do hat we would, we must be content to do what we can. Even if we had an army of health visitors or other social workers they could hardly accost passers-by with the query "Do you need help?" Clearly, then, the doctor's surgery will remain the catchment area for such cases: and rightly, for their care is a part of medicine. This being so can the doctor be given some hint to follow up, when he sees a patient for the first time? At health centres, a receptionist trained in taking social histories could be of very great service to him; her few informative lines at the top of the case-card would save him much preliminary skirmishing, and also from asking unnecessary questions. And would it not be possible for a mature and diplomatic secretary to do much the same thing for the doctor in his own surgery?

When the doctor has got the facts, what should be his next move? Sometimes he may himself be able at once to suggest the remedy—to put the patient directly in touch with a youth leader, an old people's club, a night school, a cycling club, a dramatic society, or a child-guidance clinic. More often, as things stand, he will be at a loss, simply because, at present, he has no means whatever of keeping track of the activities and services and amenities available in his area. It would, we believe, be a valuable public work on the part of the British Medical Association to make surveys of all such facilities, up and down the country, and to supply their members with local directories describing them. These directories would probably be no less welcome to medical officers of health than to doctors in practice. Where the practitioner cannot give an answer out of his own knowledge he should, in our view, get into touch, preferably by telephone, with the M O H., who should suggest the right person to give help and advice. If the M O.H. has an almoner on his staff—as many now do—he may ask her to visit the patient; or he may think the case more suitable to pass on to the education department; or he may ask the health visitor to take it over. Health visitors and almoners, however, like doctors, are going to be very scarce for many years to come. Either of them may find it impossible to see personally every patient referred to them, and we agree with Dr. HARDING that, provided it is given acceptably, they should be grateful for the help of volunteers We suggest that the health visitor should form the habit of telephoning to voluntary organisations which might help her—for example, the British Red Cross and St. John Ambulance Brigade, and the Women's Voluntary Services—and asking them to look after selected cases, reporting to her when further help is needed from her department. This system of mutual coöperation between the voluntary and municipal organisations seems more likely to succeed than any plan by which voluntary helpers are placed formally under the direction of social workers. Probably the voluntary bodies would respond well to this coöperative approach, and would make a useful study of the social amenities of the neighbourhood; moreover, the health visitor would be able to select only the cases she thought appropriate for treatment along the lines followed by the voluntary organisations. It is worth noting, besides, that in some areas there is already a council of social service which could doubtless give first-hand advice on the facilities of the area, both to doctors and health departments The present need surely is not to multiply agencies, or create competition for lay helpers, but to use more smoothly the nerves and muscles of our existing social service. *Ultimately* this can only be achieved by individuals; and under the National Health Service social medicine, far from becoming more impersonal, will depend more than ever on the ability of individuals to work together. It is for the doctor to get to know his M.O.H. as his colleague in the other department; for the M.O.H. to get to know his doctors as his colleagues in the field; for both to get to know the social amenities and services on which they can lay their hands; and for almoners and health visitors to multiply as fast as they can, since they are the eyes, ears, and tongues—the scouts, the field telephone, and the intelligence department—of the health service.

[1] *Lancet*, Sept. 27, p. 488, and Nov. 8, p 702.

Can We Afford It?

WHEN the National Health Service is discussed in relation to the country's rather shaky finances, the cry inevitably arises—can we afford it? Sometimes the man who raises this cry is under the mistaken impression that under the present system the medical services cost scarcely anything: he does not understand that most of the charge which is in future to be borne by the citizen as contributor and taxpayer now falls on the citizen as patient and supporter of charities. Even so, the question can still be fairly asked; and, putting aside all humanitarian considerations, some sort of attempt can be made to answer it. What has first to be decided is the amount of money, lost through illness, which the medical services might be expected to save. The Social Survey report on morbidity[1] shows that, in a cross-section of the population of working age, up to 18% in any month may suffer from some ailment which disables them for at least three days. The P.E.P. report on the health services[2] stated that the loss of nearly 30 million working weeks accounted for by patients included under National Health Insurance in 1933 represented a gross under-estimate of the wastage from sickness in the population as a whole; yet even this loss cost at least £60 million in the year. The total real loss is difficult to assess, comprising as it does not only the lost produce of these idle hands but also the cost of medicinal and hospital treatment and of compensatory payments. Serious as is the loss of income through illness, the death of the wage-earner is too often a financial catastrophe for his family; and the postponement of death, like the prevention of disease, is thus of economic as well as human importance.

American statisticians have lately been computing the changes in "the money value of a man" brought about by recent advances in medicine.[3] Since the turn of the century, they say, the general death-rate in the United States—and experience in this country is similar—has declined by 40% and the "expectation of life" of a man has increased by about sixteen years. (Here the term is used in its technical sense as the number of years a child born, say, in 1900 would live were the death-rates then current to continue indefinitely.) At the death-rates for 1901, about half t
men aged twenty would live to retire at sixty-five
at 1939 rates, about two-thirds would do so. If
man aged twenty had an average income of £312 p
annum, the longer working life thus implied woul
increase his expected net earnings during his care
from £6850 to £7475—i.e., by £625. Summed ov
all the men of his age-group the monetary value
the results of the application of scientific methods
prevention and treatment, is, to say the lea
impressive. The accelerated advance of the pa
fifty years may be compared to the sluggish progre
of the centuries before the age of modern medici
and hygiene. Rough calculations put the expectati
of life in pre-Christian Rome at twenty-five year
in 1691 the same expectation for the inhabitants
Breslau was, according to Halley's first life-tabl
about thirty-three years; for the American at t
middle of the nineteenth century it had risen
forty years. Most of the dramatic decrease in mortali
in the last half-century has of course been amo
infants and children; much less has been achiev
for the older man whose earning capacity is at i
peak.

Though the rapid pace of improvement in rece
years can hardly be expected to continue, a
fear that saturation-point has been reached is sure
premature. As long as essentially preventable diseas
like diphtheria exist, and as long as there are b
social gradients in mortality, whatever the caus
there is scope for fresh endeavour in the field
medical care. But, like all else nowadays, it is
question of resources and priorities: how much hav
we been prepared to devote to the task in the pas
and what of the future? Another American study
is relevant enough to pre-war circumstances here
be of interest. In the period 1935–39, it seem
4·2% of the total U.S. consumer expenditure went o
medical services of all kinds—rather less in fact tha
the outlay on either alcohol or recreation. Partly a
a result of this expenditure, however, the America
people obtained between 1900 and 1947 an increas
of seven years in the normal expectation of lif
Much of this betterment is due to a more hygieni
environment, which is to some extent a by-produc
of applied medical science, but a great deal must b
the result of new therapeutic methods. These new
methods in their turn cost money, as the risin
proportion of medical expenditure on drugs confirms
It was cheaper to treat the diabetic with codein
during his brief remaining spell of life than it is t
increase his expectancy almost to normal limits by
continued insulin medication; the opium pill an
abdominal poultice were more economical, if les
effective, means of treating appendicitis than the
whole armamentarium of modern surgery. The long-term economic benefits of efficient medical care can be drawn only if the appropriate monetary investment is made.

To morbidity, as to mortality, these general principles apply. We are being exhorted to increase production by 10%, and to this achievement much could be contributed by even a small reduction in the enormous wastage of man-power due to illness. Typical potentially fruitful fields for further research

the prevention of upper respiratory diseases, hich bulk so much larger than even the commonest dustrial poisoning, and the rapid convalescence and onomic reablement of patients recovering from ous disease as well as injury. The exploitation research in these and other sectors of medical care ill need the diversion of men, money, and materials; t economic reasons in themselves give high priority such work, and above all to further research. In e long run, as RUSKIN said, "there is no wealth t life."

Penicillin Stock Taking

PENICILLIN has passed from infancy to childhood d has successfully withstood most of the ills that ect the infant. The cynical advice to use a new ug while it still acts may have struck home here and ere, but it is a fair claim that penicillin and the lphonamides should be ranked as the two greatest ntributions to the treatment of infection since lvarsan. Inevitably, however, the virtues of peni- llin are now taken for granted, for virtue has o news value, and its deficiencies are receiving creasing attention. These deficiencies, from the ctor's viewpoint, are the need for parenteral jection, the rapid excretion so that injections have be given frequently, the need to continue treatment r 4–7 days in most infections, and the fear that the ug is not today as effective as it first was. If these stacles can be overcome there is little doubt that nicillin will become the drug of choice for a much ider variety of infections even than at present, nce the almost complete absence of toxicity, even enormous dosage, gives it a great advantage over e sulphonamides. Most of the allergic reactions e probably due to impurities and may be avoided using the purer preparations now obtainable; t at a price, since the crystalline drug is much s potent against experimental streptococcal and eumococcal infections than impure preparations.[1]

When given by mouth penicillin is poorly absorbed, ther because of the action of the gastric acid or rough destruction by penicillinase-producing bacteria the gut. But McDERMOTT and his colleagues[2] und that there was a wide variation in the acidity fasting stomach contents and that absorption of nicillin was the same in achlorhydrics and in those th acid secretion. STEWART and MAY, in this issue, ve further shown that only when the reaction of e stomach contents is below pH 3·0 is penicillin ely to be destroyed within 40 minutes and that struction by penicillinase is unlikely since the per reaches of the bowel do not ordinarily harbour nicillinase-producing bacteria. They conclude that sorption of penicillin from the alimentary canal curs mostly in the duodenum, that the drug is st given in a small bulk of 5–10% glucose which ay favour absorption in some people (and incidentally ask the bitter taste), that enteric-coated capsules ve poor results, and that if an antacid is used dium bicarbonate or citrate is preferable to the ater-insoluble substances like kaolin or magnesium isilicate. A most important finding of many orkers on the absorption of penicillin by mouth is that best results are obtained if the drug is given half an hour to an hour before breakfast or about four hours after a meal. With a dosage of 50,000 units given at these times MARKOWITZ and KUTTNER[3] found that blood-levels in 55 out of 70 children aged 6–14 years were around 0·2 unit at 30 minutes and had fallen only slightly at one hour but to just detectable levels after two hours. In the remaining 15 children absorption was more variable and in some cases as little as 2% of the drug was excreted in the urine. Blood-levels were correlated to some extent with the weight of the child. The outcome of all these investigations is that oral therapy with penicillin is practicable, provided a dosage 5–10 times that used parenterally is given and that the drug is administered on a fasting stomach—that is, before breakfast or $3^{1}/_{2}$–4 hours after a meal. The pædiatrician has found oral therapy very useful in infections in infancy; this route has been used with success in acute gonorrhœa, and recently DOWLING et al.[4] have shown that penicillin by mouth is as effective as intramuscular dosage in the treatment of pneumococcal pneumonia.

The rapid excretion of penicillin, requiring doses 3–4 hourly, may be controlled either by injecting the drug in a wax-oil excipient which gives a depot effect, or by using some substance which will dam up its excretion by the kidneys. The *B.P* preparation of penicillin in arachis oil and beeswax has not become popular, since it is difficult to inject and there has been some doubt about its safety and efficacy. The alternative method, by preventing excretion, has lately received encouragement by the discovery of another substance besides amino-hippuric acid which is apparently both safe and effective. This drug—caronamide[5]—is given by mouth and has the effect of raising the blood-levels of penicillin given by mouth or by intramuscular injection 2–7 times.

Emphasis has been laid by various workers on the need for continuing with penicillin treatment long enough to avoid any recrudescence of infection. The advantage of moderate doses continued for 3–4 weeks over much larger doses given for a shorter period was well demonstrated in the treatment of bacterial endocarditis, and many workers must have had the unhappy experience of seeing a relapse of a staphylococcal infection when therapy was stopped as soon as the temperature reached normal. But we still need more information about the value of intensive dosage of say a million units per day for 2–3 days in completely eliminating the infecting organisms—for example, in throat infections like streptococcal tonsillitis and diphtheria.

There remains the problem of penicillin-resistant bacteria, of which there are two kinds—the resistant variants of bacteria that are normally penicillin-sensitive, and organisms that have some natural resistance to penicillin—e g., *H. influenzæ* and *S typhi.* The staphylococcus is the principal, and perhaps only, pathogen with a high sensitivity to penicillin which can readily be made highly resistant in the test-tube, and there is some evidence that the proportion of resistant staphylococci causing human infection is on the increase Thus BARBER[6] has

reported two series: 200 strains of staphylococci (of which 99 were from infected lesions) examined in 1946 yielded 12·5% strains resistant to 10 units of penicillin in an agar ditch-plate; whereas of 100 tested in 1947, all from infected lesions, 38 were resistant. It is, however, important to note that 28 of the 38 resistant strains were isolated from patients who had already had a considerable amount of penicillin; in other words, they were a selected group and conformed to the view that penicillin-resistant staphylococci are found far more often in patients who have been in hospital for some time than in new admissions. Some of these strains may come from patients who have been infected with a penicillin-resistant staphylococcus after admission, as happened in BARBER's series, while in other cases they represent the survival of strains that are naturally resistant because of their capacity to produce penicillinase. In other (unpublished) series of cases examined at onset of infection the proportion of resistant staphylococci does not seem to be increasing rapidly, but obviously the danger of breeding resistant strains exists and needs attention. Two modes of attack may be suggested—to strike hard in the early stages of infection so as to knock out moderately resistant as well as sensitive strains, and if the infection does not respond within a few days to increase the dose still further; or to use combined chemotherapy of penicillin and sulphonamides (sulphathiazole is probably still the sulphonamide of choice for staphylococcal infections) with the object of preventing multiplication of the few resistant variants by the inhibitory action of the sulphonamide while penicillin is dealing with the bulk of the sensitive organisms. There is experimental backing for this second procedure,[7] which does not depend on synergism and which deserves more clinical trial, particularly in severe infections where treatment may have to be continued for a week or more. For infections due to partly resistant organisms, like the hæmophilus group, massive dosage seems to be the answer, as GOTTLIEB and FORSYTH[8] showed in their successful treatment with penicillin of a small group of cases of *H. influenzæ* meningitis. Similarly, discouraging or equivocal results in the treatment of typhoid fever with penicillin plus sulphonamides should not discourage further trials with larger doses, particularly if treatment can be begun early in the infection.

Coming Shortly

LAST week the Minister of Health met the Negotiating Committee and commented on the statement they had prepared for him. This statement, together with his written reply, will very shortly be circulated by the British Medical Association to every member of the medical profession and will also be issued to the press. Besides answering arguments put forward by the committee, the reply explains in detail how the Minister proposes to give effect to the recommendations of the Spens Committee on the remuneration of general practitioners, and deals broadly with the terms of service which will be offered them.

CHRISTMAS FOR SOME

DOCTORS are generally well remembered at Christmas Unless they have been misguided enough to choose on of the isolationist specialties, like pathology or radiolog (or medical journalism), grateful patients waylay ther with eggs, home-made wines, cheese sent by the frien abroad, and even the unforeseen goose or turkey No-one would grudge the family doctor these tokens friendship, since for most of the year he is hard-drive in the service of his patients; but he would need to b hard-bitten as well if his own deserved good fortun failed to remind him of others who are less lucky. Th Royal Medical Benevolent Fund tries to remember a those doctors and dependants of doctors—mostly ol and sick people—who are in need at Christmas, and t send those on its list a substantial Christmas cheque.

This is not an easy time for giving; but if we are a rather poor, there is the more need to lay out our mone carefully, putting first things first. The healthy hard doctor, well able to fend for himself and his family, wi hardly fail to put the fund's Christmas appeal amon the first things. The address is 1, Balliol House, Manc Fields, London, S.W.15.

INTELLIGENCE

Prof. Lewis M. Terman[1] describes two interesti pieces of American research on the development superior intellectual ability. In the first a list was mad of 300 "eminent" persons, from whose biographies the mental development was traced back to childhoo Three psychologists, intimately acquainted with the ag norms of mental performance, independently estimate the lowest intelligence quotient (I.Q.) required for th recorded childhood achievements and assessed the valu of the evidence on which the I.Q. was based. The averag of these three estimates was used in stating the result For the 300 persons the I.Q. ranged from 100 to 200 an averaged 155—i.e., more than three times the standar error above the mean of the general population. A I.Q. of 100–120 was found only when biographical detail of childhood were scanty. The mean for philosopher was highest (170). Poets, novelists, dramatists, an revolutionary statesmen came next with 160, and wer followed by musicians with 145, artists with 140, an soldiers with 125. Scientists achieved the mean for th whole group (155).

This digging up of literary fossils must be at best chancy business, apart from the fact that a biography i usually a form of hero-worship apt to exaggerate child hood performances. More satisfaction is obtainabl from the second experiment in which, in 1922, a schoo population of 250,000 was sifted to find children with a I.Q. of 140 or more. The number of such children dis covered (more than 1050) was large enough to bear statistical analysis, and it became obvious that superio intellectual ability was associated not only with superio personality and character but also with superior physique But the experiment did not stop there, for the history of those children has been followed. When they were retested in 1928 and 1936 the figures indicated that, in comparison with the general population, the rates of mortality, insanity, and divorce were low, while the suicide-rate was about the average. By 1940 71% had married and produced about 780 children, of whom 384 over the age of two years yielded a mean I.Q. of about 127, representing the expected regression towards the mean of the general population. In 1946 the mortality and insanity rates were still lower than those of the general population, and the delinquency-rate "extraordinarily m"; about 85% of either sex had married (a rate far ore that prevailing among U.S.A. graduates) and they d produced more than 1500 children—not enough to aintain the stock. The average quality of these ildren, however, is considered very superior, the roportion of mental deficiency being about half, and e proportion with an I.Q. of 150 or more being many mes that for the general population. Plans are being ade to continue the follow-up of the entire gifted group til 1970 at least.

AGAINST RHEUMATISM

DURING the past year the Empire Rheumatism uncil has extended still further its activities and fluence. At the annual meeting in London last week rd Horder, the chairman, told of a Canadian Arthritis d Rheumatism Society which is being formed along e lines of advice offered by the council. Dr. C. B. Heald trying to arrange for the formation in New Zealand an official Rheumatism Council in association with the mpire body, while steps to inaugurate a similar council Australia are envisaged. The European branch of the ternational League against Rheumatism are interested making the council's journal, the *Annals of the umatic Diseases*, the vehicle for their activities; d the American branch of the league are proposing to opt the *Annals* as their official journal in association th the council.

Turning to research and teaching, Lord Horder said at fourteen "registrars" are now working on the vestigation into the factors causing rheumatoid thritis. The council's laboratory at the Hospital of S. John and Elizabeth, London, has been reopened, and research-worker has been appointed to study the lergic aspects of rheumatism. During the past year o successful postgraduate courses have been held. he rheumatism committee formed by the National al Board and Miners' Welfare Committee agreed to commend that the pilot survey into the incidence and uses of rheumatism among miners, suggested by the uncil, should be undertaken in certain coalfields; and e rheumatism research department of Manchester niversity will be approached to carry out this work.

Lord Horder was also able to show that the council s used its influence with profit in the field of adminis- ration. The Ministry of Food has acceded to a suggestion at extra milk should be allowed to sufferers from tive rheumatoid arthritis, and the Ministry of Labour s agreed that chronic arthritic patients should be ccepted as eligible for admission to the new reablement entres and "Remploy" factories, on the same terms as hose applicable to sufferers from chronic tuberculosis d chronic cardiac disease.

CURRENCY FOR TREATMENT ABROAD

THE Treasury have appointed a committee, known s the Exchange Control Medical Advisory Committee, o advise on cases meriting foreign exchange for treatment broad. It has been decided that in the present economic ituation foreign currency will be granted on health rounds only to applicants who can satisfy the committee hat this currency is needed to obtain abroad medical or urgical treatment which offers a reasonable prospect of ure and which cannot be got in either the United Kingdom or the rest of the sterling area (the British Empire except Canada and Newfoundland, Iraq, Transjordan, Iceland, and the Faroe Islands). Previously urrency was granted on the presentation of a medical ertificate stating that life would be endangered if the patient did not go abroad; but this phrase has proved to be open to loose interpretation.

It is intended that the new rule should be strictly interpreted, and since almost all forms of treatment are to be had in this country it follows that very few applications will be approved. Probably most cases coming under serious consideration will be of tuberculosis, owing to the shortage of tuberculosis beds in this country. The essential consideration will be whether the patient will recover if he is allowed to go abroad for treatment, and it is in consequence thought that such cases as these will qualify: early localised tuberculous infections with definite pulmonary and glandular manifestations; exudative pleurisy after absorption of the fluid; recent fibrosis relatively small in extent; unilateral cavitation: and certain conditions, not necessarily pulmonary, requiring special surgical technique unobtainable in this country. Cases of chronic ill health will not be considered unless there is a good prospect of recovery.

Doctors who think they have suitable cases are asked to send full clinical details, X-ray films, reports of special investigations and of consultants' findings, and an explanation as to why the patient cannot be suitably treated in the sterling area to the secretary of the committee, Tavistock House North, Tavistock Square, London, W.C.1. Normally a consultants' fee of four guineas will be payable. If the committee agree that the case is suitable they will provide a certificate on which the patient's bank will obtain the necessary currency.

HOSPITAL CARE IN THE UNITED STATES

THE report of the Commission on Hospital Care in the United States has now been published.[1] It is the most ambitious attempt yet made in America to blueprint a "coördinated national plan for the future development of the hospital service." The commission, established in 1944 by the American Hospital Association, has conducted an intensive two-year survey of general hospitals in the United States. Voluntary agencies collaborated with the United States Public Health Service, and the present report may therefore be regarded as an authoritative indication of the line that official policy is likely to take. From the first it was recognised that the making of detailed surveys would have to be delegated to the various States, and a great effort has been made to stimulate activity. Michigan led the way, and the staff of the commission undertook the detailed survey in that State as a pilot study, the report of which has already appeared.

The report will go down to history as marking public recognition of the lack of system in hospital organisation in America and the need to remedy it. Some strong phrases are used, reminiscent of much of the public debate in this country which preceded the National Health Service Act: "we refer to our splendid system of hospitals, whereas actually there is none." The current programme of supervision has had a wholesome influence, but it has "not resulted in effective controls." This will not do: "hospitals are now on the threshold of a period of development which will mark the beginning of a new era in the advancement of human welfare." There is a tendency to the platitudinous, perhaps inevitable in a document of this kind. Excellent precepts abound: "general hospitals should coördinate their efforts with those of other community agencies"; "the medical staff should maintain vigilant supervision and continuing evaluation of the quality of medical care in the hospital"; "schools of nursing should be organised on a sound educational basis." But one will search in vain for light upon the fundamental problems which in America as in this country are likely for some time to come to baffle all our best efforts. The report skims lightly over the problem of the shortage of nurses, which is probably even more acute in America than it is here. The reader will find only a reflection of current opinion and no real recognition that shortage of nurses is likely to nullify the greater part of the effort now being put into the establishment of optimum ratios of beds to population. The detailed discussion of this subject is based on the use of the "bed-death" ratio to determine the need for hospital beds in a given community. The method, which was used in connexion with the Michigan survey and also in the independent "Master Plan for Hospitals in New York," probably deserves more attention than it has so far received in this country.

---

[1] Hospital Care in the United States: Commission on Hospital Care. New York: Commonwealth Fund. Pp. 631. $1.50. To be published in Britain by Oxford University Press.

In the long historical section the statement that "in the eighteenth century well managed hospitals, organised nursing, and the charitable care of the sick had largely disappeared in Protestant countries" cannot be allowed to pass. It was in the early eighteenth century that the example of the Dutch hospital system, combined with religious motives, led to the foundation of a notable group of hospitals in London (from 1720 onwards), in the English provincial cities (from 1736 onwards), and in Edinburgh (1741). It would be strange indeed if this movement was in no way connected with the foundation of the first voluntary hospital in Philadelphia in 1751 and of the first medical school in 1765. The statement that "European hospitals reached the lowest level of service in history in the eighteenth century" does less than justice to the pioneers to whom American voluntary hospitals today, as well as our own, owe so much.

MENTAL HOSPITALS FROM WITHIN

VISITORS—even medical visitors—to public mental hospitals are often disturbed by the drab and sordid appearance of the buildings and wards, no less than by the disheartened look of the patients. It is usual, on such occasions, to suppose that the patients, lost in the preoccupations of their illness, are unaware of all that strikes the visitor so painfully. Two recently published books dispel this comfortable fancy. *The Kingdom of the Lost*, by J. A. Howard Ogdon,[1] and *Certified*, by H. C. Woodley,[2] are accounts, by men who have been certified patients, of life in two of our public mental hospitals, one Scottish, one English. Both writers—Mr. Woodley outspokenly, Mr. Ogdon in passing—insist on the need for drastic reform; both tell of the added weight imposed on the sick mind by cheerless surroundings—often cold, often dirty—by the company of large numbers of fellow patients, some dirty and degraded, many deeply depressed by their inability to escape from such hateful captivity, and by the insensitive behaviour of the scarce and overworked nursing staff. Far from being unaware of such things, patients suffer mentally because of them, and may even fail to mend because they feel their cause is hopeless. After many years in such surroundings—and residence in mental hospitals is more often measured in years than months—even a healthy mind would suffer. Perhaps the most depressing passages in these books are the accounts, too simple and circumstantial to be disregarded, of the filthy conditions in lavatories and washrooms. In the older mental hospitals sanitary arrangements are barely adequate, but can be made to do if staffing is complete. Nowadays, when mental hospitals are suffering more severely than any other type of hospital from lack of nurses and domestic staff, it is clear that sometimes no pretence of hygiene or even tolerable cleanliness is maintained.

Many other points in which these writers corroborate each other will disturb the complacent. They are agreed, for example, that sedatives were the only form of treatment widely used. Mr. Ogdon says: "I must be quite definite in saying that the average 'public-assisted' patient got no treatment at all for his mental affliction. Only dope was available;" and Mr. Woodley, after a distressing account of the administration of a sedative to a patient who refused to swallow, goes on to say "So it is with him and with many more: violence—dope, violence—dope, and so on—to the inevitable end.' Both tell of uninterested doctors, and of the apathy which succeeds hope—"the deadly boredom of a mind having nothing to 'chew.'"

The implications are clear enough: standards i some of our mental hospitals are now very low, and unless the nursing crisis is handled successfully they ar in danger of falling to the level from which such men a Tuke reclaimed them.

IMMUNISATION AGAINST INFLUENZA

THE background of the recent decision to vaccinate al personnel of the United States Army against influenza was outlined by Prof. Francis G. Blake, of Yale University, in an address last month to the New York Acad of Medicine.

Between Oct. 19 and Dec. 4, 1943, 6263 students i nine universities were vaccinated subcutaneously wit 1 ml. of a formolised allantoic fluid eluate, type and B ten-times concentrated vaccine, made up of PR8 and Weiss A strains and the Lee B strain of virus at the same time 6211 controls were injected with comparable material, excluding the virus. Epidemics o influenza A developed in all these institutions in lat November or early December. In the whole group th incidence of influenza during the epidemic was 2·22 among the vaccinated, compared with 7·11% in th controls. Resistance, it was found, developed abou eight days after vaccination. During the autumn o 1945 the efficacy of this vaccine against influenza B wa tested. At one centre the incidence among the vaccinated was 1·15%, compared with 9·91% in the unvaccinated; and at another centre the attack-rate in th vaccinated was 0·5%, compared with 12·5% in the unvaccinated.

Thus, said Professor Blake, considerable success wa achieved against both influenza A and influenza B unde these conditions: (1) *with the use of a potent formolised and concentrated vaccine, in a single dose of 1 ml subcutaneously and capable of stimulating an antibody response comparable to that which develops early in convalescence*; (2) when the antigenic structure of the strains of virus used in the vaccine was closely similar to that of the strains causing the epidemics; and (3) when vaccination had been carried out within 1–6 weeks before the onset of the epidemic.

More recent trials have been less satisfactory. In an epidemic last March, apparently due to virus A with a sharp antigenic deviation from the standard PR8 strain, the vaccine failed to protect persons vaccinated four months previously; and Francis, Salk, and Quilligan attributed this failure to insufficient antigenic crossing between the strains in the vaccine and the prevalent epidemic strain. Similar unsatisfactory results were obtained about the same time among Army personnel and at Yale. Nevertheless, Professor Blake concluded that "it would not appear outside the realms of possibility that the resistance of the population as a whole may be maintained at a level sufficient to forestall and prevent another disastrous pandemic."

FROM October next women will be admitted to membership of the University of Cambridge on the same terms as men. They will thenceforward take full degrees instead of the title of these degrees, and will be eligible for nearly all university offices, including that of vice-chancellor.

WE have to record the death on Dec. 5 of Dr. R. A. FLEMING, consulting physician to the Edinburgh Royal Infirmary and a former president of the Royal College of Physicians of Edinburgh. He was 85 years of age.

THE URGENT NEED FOR REFORMS IN HOSPITALS

L. A. PARRY
M.D. Lond., F.R.C.S.
CONSULTING SURGEON, ROYAL ALEXANDRA HOSPITAL FOR SICK CHILDREN, BRIGHTON; LATE GROUP OFFICER, E.M.S. (1939–46)

IN too many hospitals an essential fact is forgotten—that they were founded not for the benefit of doctors, nurses, or committees of management but to help to restore the patients to health.

Enormous improvement on the social side of hospital treatment is needed. The social treatment of the patient means providing for his comfort, happiness, amusement, occupation, and general welfare, which at present are too often forgotten or relegated to a subordinate position. This social medicine means so much to a patient. It not only helps and accelerates his recovery but also brings it about in a much less irksome manner.

To obtain a satisfactory system of social medicine, at least three things are necessary. First, the medical staff of a hospital must take a great deal more interest and have a much greater say in the matter of hospital management than they have at present. They must see that their patients are sympathetically treated, properly fed, occupied and amused, and made as comfortable and happy as possible. A great deal more than mere medical and surgical directions and treatment is required of them.

Secondly, we need a radical alteration in the way committees of management are elected and carry on their work. We need the members to be selected because of their suitability and their knowledge of hospital routine and procedure. Too often now we have a committee composed of excellent people totally unfitted for their position. They know nothing of hospital management and consider their duties adequately performed if they attend a meeting once a month, sit still and say nothing, and finish by having tea with the matron. They never enter the wards and know nothing of the way patients are fed, nursed, or treated. We need chairmen who are independent and strong, not those content to approve of everything suggested by the matron, having no views of their own, and merely acting as her mouthpiece.

Thirdly, we want a much more sympathetic and understanding nursing service. Nurses should know something at least of psychology, and should recognise that a patient is a human being, living in unhappy and unusual surroundings, who is craving for kindness and sympathy. He must not be merely a case. The matron should hold modern, not antiquated, views, should be trained in human understanding and psychology as well as nursing, and should be of a nature in which sympathy, affection, and kindness are predominant.

In a few, I am afraid a very few, hospitals all these three desiderata are found. We should not be content till all hospitals reach this standard.

VISITS TO PATIENTS

A visit from a friend is often the one event of an otherwise weary day that is most looked forward to. Arrangements for visits to hospitals by friends of the patients vary very much. The up-to-date progressive hospitals allow a daily visit. The backward out-of-date hospitals still keep to Sundays and Wednesdays. There should be no difficulty in arranging visits every day of the week; it is simply a question of ward routine.

If frequent visits are of advantage to adults how much more are they to children separated from their parents and in strange new surroundings, often with very little love or sympathy, and longing for a sight of familiar faces. Two arguments have been advanced against the practice. First, it has been urged that there is a serious risk of infection conveyed by visitors. But infectious diseases, such as scarlet fever and measles, for all practical purposes can be conveyed only by those who have the infection on them, not by those who have merely been in contact with the disease, and naturally those who are actually infectious would not visit the hospital. When infection does take place in a children's ward it is due to the admission in error of a child in the incubation period, not to visitors. In nursing-homes where parents are allowed to visit their children morning, afternoon, and evening those responsible are not obsessed with the bogy of infection, and practice has proved they are justified. Why this differentiation between the two kinds of institutions?

At Worthing Hospital, where for six years daily visits to the children's wards have been permitted, there has been no increase whatever in the incidence of infection. Parents are allowed to visit their children daily and not at a set time to suit the nurses, but at a variable time to suit the mothers, an arrangement which is found to work most satisfactorily and is very helpful to the nurses. Mrs. Jones comes to visit her little Sally, she reads to her an interesting tale. Soon all the ward is listening and interested, enjoying the story. The children are occupied and happy and the nurses are free to carry on their work, temporarily relieved of the care of the children. How ideal this would be if adopted by all children's hospitals.

The doctors responsible for the plastic-surgery clinic in Wellington, New Zealand, have for five years allowed mothers not only to visit the hospital when they wished, subject to reasonable regulations, but also to remain there, going home when necessary. In a plastic-surgery clinic the avoidance of infection is doubly important. Here again results have justified progressive action. No single case of cross-infection has occurred during those five years. The same arrangements have been made in one of the New York children's hospitals, with equally satisfactory results.

At one children's hospital where I tried to get the committee to allow a daily visit I was met with the stereotyped theoretical objections, the grave danger of infection and of psychological trauma. How, in the face of such dangers, the committee could reconcile it with their duty to the children under their care to allow them to run the risks on Wednesdays and Sundays passes my comprehension. For five days the risks must not be run; for two days the committee complacently decided it might. At this hospital there is a notice-board outside inviting any casual passer-by to come in and inspect the hospital. They are allowed in the wards when the mothers of the children are refused. Friends of the staff and committee are constantly taken round. How is it possible to justify these things if the terrible risks of infection really exist?

In a report issued by the British Pædiatric Association on cross-infection in children's wards, among the many precautions advocated there is no suggestion that visits by parents should be forbidden.

The second argument is that visits upset the children and do them harm. But it is found in practice that a daily visit, something to be looked forward to at frequent intervals, is far less upsetting to children than the two-days-a-week plan with its long gaps between. This has been the experience of those hospitals which are sufficiently progressive. The matron uses her discretion where difficult children are concerned. A tactful talk with the mother always ensures coöperation: she keeps away if this is considered advisable.

The medical officer of a well-known hospital writes me as follows:

> "The children's hospital here is an annexe of the Royal Infirmary, and I am in complete charge of the medical ward and oversee the general health of the children in the two surgical wards.
>
> "It is true that in the medical ward there are cubicles and barrier nursing is more strictly enforced; but, on the other hand, there are many more children with infectious conditions admitted.
>
> "I do not remember ever having known a child to be directly infected by visitors. Psychologically the benefits are sometimes enormous and perhaps even life-saving.
>
> "There may be some prejudice to overcome among the senior nurses, but the benefits of visitors soon become so obvious that this is soon dispelled."

It is high time that those hospitals which are behind the times with their procedure and reluctant to put their house in order should be compelled to do their duty to the children in their charge. It is to be hoped that this will happen when the National Health Service Act comes into force and new and up-to-date committees of management are appointed.

OUTPATIENT QUEUES

The long weary waiting in the outpatient department is a real and outstanding grievance. It is remarkable that the long-suffering victims have submitted to it for so long. This waiting period is in many hospitals two or three hours, in some four or five, and in one local hospital even six hours, and then the patients are sometimes sent away and told to come another day. This leads to much resentment.

In many hospitals it is still the practice to summon all patients for the day at the same time. Forty, fifty, or more are crowded in the small waiting-hall, many of them not even able to sit down. The first patient is seen as soon as the doctor arrives, but he has probably been waiting a long time, having come early to obtain a good place in the queue.

This is all wrong. It can be put right by a system of outpatient appointments by which each person is given a fixed time to attend. No extra work falls on the doctor; he sees the same patients, but instead of a great surge at the beginning there is a steady stream throughout the session. The long, weary, unnecessary waiting is reduced from hours to minutes.

The change needs common sense and determination on the part of those responsible. Guy's, the Jewish Hospital, the Birmingham Accident Hospital, the Royal Sussex County Hospital, the New Sussex Hospital, and many others have adopted this procedure to the satisfaction of all concerned.

> I recently visited a hospital noted for the long time its outpatients were kept waiting. I had been urging for some years the advantages of an appointment system, with no success.
>
> There were about 70 people crowded into a small waiting-hall. The matron said to me with a triumphant smile: "All by appointment."
>
> I find it difficult to understand how a woman who had reached the important position of matron could imagine that to make appointments for 70 people at the same time was a solution of the problem.

EARLY WAKENING

The time at which patients are wakened for washing varies considerably in different hospitals. In eight hospitals in one area the official time varies between 5 and 7 A.M.; but unfortunately this official time is not always kept and there are plenty of instances in which patients are roused at 3.30 to 4 A.M. This is clearly very bad practice. Rest and sleep are very important to the sick. It is essential that his uneventful and monotonous day should start well, and that he should not be deprived of any of his natural sleep, so importan for uninterrupted recovery.

The only reason for this practice of early waking i to allow the nurses to get ready for the doctor's visits. A simple rearrangement of hours of work and of duties which can be carried out with little difficulty provide those responsible show good will and determination would put the matter right. The proper time shoul be about 6.30 or 7 A.M. This is a reasonable hour, whic obtains in many hospitals satisfactorily, and there i no reason whatever for waking patients at an earlie hour than this in any institution.

WAITING-LIST FOR OPERATION

Another factor causing patients much anxiety an strain is the long wait between the decision of the surgeon that an operation is necessary and admission to hospital. Many hospitals have a long list of patients awaiting admission, mainly for operation. The chief surgeo of one hospital in the Midlands told me recently tha at his hospital the waiting-list often exceeded 100 In one of our local hospitals a patient was told i July that she needed operation and that her nam would be put on the waiting-list and would probabl be reached by December. This is no isolated instance. This long period of anxiety is harmful to patients, an in many cases, especially those of cancer, destroys th hope of cure.

The delay is largely due to lack of beds, and the pro- vision of extra beds is an urgent necessity. But unti this happy state of affairs comes about somethin can be done. Other neighbouring hospitals can an will help. The one with no waiting-list and empty beds will help the one with a waiting-list and full beds. Recently a local hospital found itself with 65 patients urgently needing operation. With the willing and friendly assistance of a neighbouring hospital the list was completely cleared in less than a fortnight. Hospita surgeons do not like parting with their patients, nor patients with their surgeons, but the good of the sick person should come before everything.

HOSPITAL DIET

Proper meals mean a great deal to all of us, and something more than a great deal to the sick. By proper meals I mean, first, a meal selected for its nutritional, digestive, and appetising qualities, suitable to the particular patient and given in proper quantities; secondly, a well-cooked meal; and, thirdly, a meal properly served. Meals should not be lukewarm, but hot; the little amenities of the table should be observed; the crockery, glass, and tray cloths should be bright and clean; tea should not be slopped over in the saucer; and attention should be given to the many other small points which go to make a meal attractive and appetising. To carry this out requires good cooks, nurses determined to see that meals are nicely served, and, above all, someone in authority to keep a constant watch on the service of meals throughout the hospital.

Diet is too often inadequate. Neither the patients nor the nurses are supplied with enough food. King Edward's Hospital Fund for London recently investigated the matter in three hospitals in Greater London and found that in two of them the diet was inadequate. The investigators stated that, in spite of recent improvements, hospital diet was not all it should be in quantity and quality, in nutritional standards, and in matters of preparation and service.

The importance of diet is summed up in this quotation from a booklet recently issued by the Ministry of Health:

> "Experience has shown that the food provided in many hospitals is unsuitable, badly cooked, and badly served, with the result that the patient's recovery is delayed. Waste, too, is common.

"It is desirable that some person should be in supreme charge of all the feeding arrangements, including catering, cooking, and service, both for patients and staff. His responsibility must necessarily be delegated to several subordinates, but his control should be real, and not, as so many hospitals, merely nominal.

"At the same time every medical officer should be taught realise that he is as much responsible for the proper feeding of the patients under his care as he is for their proper nursing and treatment.

"Suitable meals, well cooked and attractively served, constitute just as important a part of the treatment as careful nursing and skilled medical attention."

ENVOI

In making these suggestions for the improvement our hospital administration and régime I am advocating nothing new or impracticable. The work done by hospitals is magnificent, but no-one can say it is perfect, and I am not so foolish as to say that carrying effect my suggestions would make them perfect. first-class hospitals have already adopted these reforms; our second-class have adopted some; our third-class, none. Unfortunately, first-class hospitals are in very considerable minority.

Each one of these reforms is a step forward, each for the advantage of the patients and the hospital; if they were universally adopted, the recovery of sick would be pleasanter, happier, quicker, and more complete. There is a wonderful opportunity for the new regional hospital boards. Let us hope they will use it to full.

AVOIDABLE MENINGITIS

MEMORANDUM FROM THE PUBLIC HEALTH LABORATORY SERVICE AND THE LONDON SECTOR PATHOLOGISTS' COMMITTEE

EVERY operative procedure entails some risk to the patient, but in simple operations like spinal puncture the risk ought to be practically negligible. The occurrence of meningitis following the withdrawal of cerebrospinal fluid or the administration of a spinal anæsthetic a grave reflection on the methods used in many hospitals, because these "accidents" can be avoided by the adoption of a simple and reliable technique. That such a technique is not in fact universally employed is attested by the number of cases of avoidable meningitis reported in the literature during the past few years. Furthermore, as Garrod (1946) points out, "there is a natural reluctance to publish anything which may appear discreditable. . . . It is therefore probable that meningitis following spinal anæsthesia has been far commoner than the literature of the subject would suggest." This statement is endorsed by surgeons and anæsthetists whenever the subject comes up for discussion.

NATURE AND SOURCES OF INFECTION

This memorandum is not concerned with meningitis secondary to some primary infective focus already present the patient at the time of operation. It refers solely meningitis that results from the direct inoculation of micro-organisms into the spinal canal. The organisms most frequently incriminated are *Pseudomonas pyocyanea* and related organisms which can multiply in water at room temperature; less frequently staphylococci and other skin contaminants may be responsible. Some of the water bacteria fail to grow in ordinary culture media incubated at 37°C; hence many cases have been diagnosed as irritative or aseptic meningitis which were probably the result of bacterial infection of the meninges. Organisms normally regarded as non-pathogenic may produce infection if they gain access to the very susceptible meninges.

The *sources* of contamination may be listed as follows: (1) apparatus inefficiently sterilised or contaminated during use; (2) "sterile" water or saline used to rinse the apparatus; (3) hands of operator and assistants; (4) skin of patient; and (5) anæsthetic, antibiotic, or other solutions.

PREVENTIVE MEASURES

The ideal would be to adopt the full aseptic ritual of a surgical operation for every spinal puncture. In many cases the time and place render this impossible. The following recommendations are therefore offered, not necessarily as ideal procedures but as practical methods applicable in nearly all circumstances.

1. *Apparatus.*—If facilities are available, all apparatus including manometer should be enclosed within suitable containers and sterilised either by autoclaving at 15–20 lb. pressure for 20 minutes or by dry heat at 160°C for an hour. The complete outfit can then be held ready for use at any time. If dry heat is used, the rubber tubing of the manometer should be sterilised by boiling. For syringes and needles dry heat is preferable but ordinarily necessitates the use of all-glass syringes. (Glass syringes with metal nozzles which will withstand dry heat at 160°C for two hours are now being manufactured.) Full details of these methods, together with recommendations for a hospital syringe service, are given by the Medical Research Council (1945).

If autoclaving or dry-heat sterilisation cannot be employed, all apparatus should be sterilised immediately before the operation by boiling for five minutes, preferably in distilled water. A steriliser with a perforated lift-up tray should be used; at the end of boiling the tray is removed, placed in the inverted lid, covered with a sterile towel, and left to cool. In the occasional emergency which may arise in the patient's home a perfectly clean saucepan with a lid may be used. After boiling, the water should be drained off and the saucepan left with the lid on until cool. Methods of chemical disinfection such as soaking in spirit should *not* be used.

2. "*Sterile*" *Water and Saline.*—These probably constitute the greatest source of danger. Hospital supplies are frequently contaminated either from inadequate sterilisation initially or from contamination during previous use (Smith and Smith 1941). Thus the Winchester bottle of "sterile" distilled water or saline, used repeatedly until empty, has frequently been incriminated as the source of water bacteria found in contaminated or infected cerebrospinal fluid. If apparatus is sterilised as recommended above, rinsing and cooling solutions become quite unnecessary and their use should be abandoned.

3. *Hands of Operator.*—The operator should scrub up as for a major operation, or alternatively should don dry sterile surgical gloves. When gloves are not available it is important that his hands be dry before he handles any apparatus; this may be accomplished by rinsing with industrial spirit and/or drying with a sterile towel. Where needle and syringe have to be assembled, the needle should be handled with sterile forceps. From this point onwards the operator should touch nothing except the sterile instruments and the skin of the patient until the operation is finished. The trocar when withdrawn should be laid on a sterile towel; otherwise it may infect the spinal fluid if it is introduced again to clear the needle.

4. *Skin of Patient.*—Thorough washing with soap and warm water followed by thorough, not perfunctory, swabbing with tincture of iodine or 70–90% alcohol will leave little risk of contamination of the needle by the patient's skin. The area treated should be the entire area exposed and the skin should be quite dry before puncture is made.

5. *Anæsthetic and Antibiotic Solutions.*—No cases of meningitis have been traced to the presence of bacteria in anæsthetic solutions contained in sealed glass ampoules. Such ampoules are preferable to rubber-capped bottles intended for repeated use.

The sterilisation of the outer surface of an ampoule is difficult and attended with such pitfalls that it is

The medical officer of a well-known hospital writes me as follows:

> "The children's hospital here is an annexe of the Royal Infirmary, and I am in complete charge of the medical ward and oversee the general health of the children in the two surgical wards.
>
> "It is true that in the medical ward there are cubicles and barrier nursing is more strictly enforced; but, on the other hand, there are many more children with infectious conditions admitted.
>
> "I do not remember ever having known a child to be directly infected by visitors. Psychologically the benefits are sometimes enormous and perhaps even life-saving.
>
> "There may be some prejudice to overcome among the senior nurses, but the benefits of visitors soon become so obvious that this is soon dispelled."

It is high time that those hospitals which are behind the times with their procedure and reluctant to put their house in order should be compelled to do their duty to the children in their charge. It is to be hoped that this will happen when the National Health Service Act comes into force and new and up-to-date committees of management are appointed.

OUTPATIENT QUEUES

The long weary waiting in the outpatient department is a real and outstanding grievance. It is remarkable that the long-suffering victims have submitted to it for so long. This waiting period is in many hospitals two or three hours, in some four or five, and in one local hospital even six hours, and then the patients are sometimes sent away and told to come another day. This leads to much resentment.

In many hospitals it is still the practice to summon all patients for the day at the same time. Forty, fifty, or more are crowded in the small waiting-hall, many of them not even able to sit down. The first patient is seen as soon as the doctor arrives, but he has probably been waiting a long time, having come early to obtain a good place in the queue.

This is all wrong. It can be put right by a system of outpatient appointments by which each person is given a fixed time to attend. No extra work falls on the doctor; he sees the same patients, but instead of a great surge at the beginning there is a steady stream throughout the session. The long, weary, unnecessary waiting is reduced from hours to minutes.

The change needs common sense and determination on the part of those responsible. Guy's, the Jewish Hospital, the Birmingham Accident Hospital, the Royal Sussex County Hospital, the New Sussex Hospital, and many others have adopted this procedure to the satisfaction of all concerned.

> I recently visited a hospital noted for the long time its outpatients were kept waiting. I had been urging for some years the advantages of an appointment system, with no success.
>
> There were about 70 people crowded into a small waiting-hall. The matron said to me with a triumphant smile: "All by appointment."
>
> I find it difficult to understand how a woman who had reached the important position of matron could imagine that to make appointments for 70 people at the same time was a solution of the problem.

EARLY WAKENING

The time at which patients are wakened for washing varies considerably in different hospitals. In eight hospitals in one area the official time varies between 5 and 7 A.M.; but unfortunately this official time is not always kept and there are plenty of instances in which patients are roused at 3.30 to 4 A.M. This is clearly very bad practice. Rest and sleep are very important to the sick. It is essential that his uneventful and monotonous day should start well, and that he should not be deprived of any of his natural sleep, so importan for uninterrupted recovery.

The only reason for this practice of early waking i to allow the nurses to get ready for the doctor's visit A simple rearrangement of hours of work and of duties which can be carried out with little difficulty provide those responsible show good will and determinatio would put the matter right. The proper time shoul be about 6.30 or 7 A.M. This is a reasonable hour, whic obtains in many hospitals satisfactorily, and there i no reason whatever for waking patients at an earli hour than this in any institution.

WAITING-LIST FOR OPERATION

Another factor causing patients much anxiety an strain is the long wait between the decision of the surgeo that an operation is necessary and admission to hospita Many hospitals have a long list of patients awaiti admission, mainly for operation. The chief surgeo of one hospital in the Midlands told me recently th at his hospital the waiting-list often exceeded 100 *In one of our local hospitals a patient was told i* July that she needed operation and that her nam would be put on the waiting-list and would probabl be reached by December. This is no isolated instanc This long period of anxiety is harmful to patients, an in many cases, especially those of cancer, destroys th hope of cure.

The delay is largely due to lack of beds, and the pr vision of extra beds is an urgent necessity. But unti this happy state of affairs comes about somethin can be done. Other neighbouring hospitals can an will help. The one with no waiting-list and empty bed will help the one with a waiting-list and full beds Recently a local hospital found itself with 65 patient urgently needing operation. With the willing an friendly assistance of a neighbouring hospital the li was completely cleared in less than a fortnight. Hospita surgeons do not like parting with their patients, no patients with their surgeons, but the good of the sic person should come before everything.

HOSPITAL DIET

Proper meals mean a great deal to all of us, and something more than a great deal to the sick. By proper meals I mean, first, a meal selected for its nutritional digestive, and appetising qualities, suitable to the particular patient and given in proper quantities secondly, a well-cooked meal; and, thirdly, a meal properly served. Meals should not be lukewarm, but hot; the little amenities of the table should be observed; the crockery, glass, and tray cloths should be bright and clean; tea should not be slopped over in the saucer; and attention should be given to the many other small points which go to make a meal attractive and appetising. To carry this out requires good cooks, nurses determined to see that meals are nicely served, and, above all, someone in authority to keep a constant watch on the service of meals throughout the hospital.

Diet is too often inadequate. Neither the patients nor the nurses are supplied with enough food. King Edward's Hospital Fund for London recently investigated the matter in three hospitals in Greater London and found that in two of them the diet was inadequate The investigators stated that, in spite of recent improvements, hospital diet was not all it should be in quantity and quality, in nutritional standards, and in matters of preparation and service.

The importance of diet is summed up in this quotation from a booklet recently issued by the Ministry of Health:

> "Experience has shown that the food provided in many hospitals is unsuitable, badly cooked, and badly served, with the result that the patient's recovery is delayed. Waste, too, is common.

y in American and Canadian hospitals, with its dance of labour-saving devices, reflects the attention to the subject by the hospital administration, it is apparent that in this respect also hospitals in country have much leeway to make up.

SERVICE OF MEALS

the items so far discussed American hospital catering ecisively ahead of our own. In one other important ter, however, the arrangements seem to fall far short rs. In our hospitals the actual service of food to patients is the responsibility of the nurse. In America separation of responsibility for catering has meant in most hospitals the service of the food has been n out of the hands of the nurse and transferred to controlled by the dietitian. The ward kitchens which the food is served and the staff working them in every instance in the United States the responty of the dietitians, and it was in this in most itals that the system appeared to fail. In most itals trays are set by "diet aids" and carried by n to the patients from the trolleys. In theory this e is supervised by a dietitian, but in practice there hen no check, and it sometimes appeared that the ice of food was careless and the meal unappetising. e a patient required help in adjustment of pillows e feeding, the tray was placed on the bedside locker left until a nurse was available. Quite often there ed to be a long lapse of time during which the food cooling, and sometimes, when there was a serious tage of nurses, the food must have been quite cold. dietitian cannot be responsible for raising patients bed or for spoon-feeding the sick. She has not the essary knowledge of the patient's condition for first, nor the time nor staff at her disposal to feed the pless. Moreover the nurse who has no responsibility the patients' meals often fails to realise the importance proper nourishment in their treatment. This is increasly realised to be a serious defect: it not only leads to te but also in part nullifies the effort which has been into the preparation of the food.

The point touches most closely the patients in the inary wards. Though the service in the numerous des of private accommodation, which plays such a part in the American hospital system, may be paratively satisfactory, the service of the food to patients in the ordinary wards falls below the dards here. Each patient is provided with a tray, the crockery is invariably very thick and heavy, the imum of cutlery is used, and the service—owing to lack of trained staff and the extent to which the vice is entrusted to maids without sufficient superon—is rough and ready. These observations strongly est that, whatever changes are made, it is most rable to retain the system whereby the nurse is ponsible for handing the patient his meals and ending to all those little adjustments which call for ividual care and attention.

BURSARS IN HOSPITAL CATERING

How soon, one may ask, is it reasonable to hope that pitals in this country will be able to overtake arrears? ch help has already been given by King Edward's spital Fund for London and its dietetic advisory vice, and by the similar service offered by the Ministry Health. Further progress is hampered not so much the quantity or quality of the food available as by lack of skilled personnel, and especially of persons petent to organise the catering service in a large pital. The work calls for managerial qualities of a h order, for it involves not only the refinements pected in commercial catering but also a practical nowledge of nutritional principles involved in the restoration of the sick to health. An interesting experiment financed by the King's Fund is now going on. A small group of carefully chosen "bursars" in hospital catering are now undergoing training at the London Hospital, and it is to be hoped that in due course as they become available to take up appointments they will powerfully reinforce the efforts of the catering officers already appointed by many hospitals.

CLASSIFICATION OF HOSPITALS

SOME time ago the Essex Hospitals Joint Advisory Council set up a subcommittee to consider the local implications of the report of the surveyors of the hospital services of London and the surrounding area.[1] This has adopted the hospital districts indicated by the surveyors, and it advances its own scheme for the organisation of hospitals within the districts.[2]

Besides linked local or general-practitioner hospitals every district, the subcommittee holds, should have a "district hospital" or "hospital centre," which might in fact consist of more than one hospital; both the linked local hospitals and the district hospital would be under a single management committee. Each district hospital might make provision for general medicine, general surgery (including children), normal maternity, fractures, dermatology, ophthalmology, and ear, nose, and throat work, and to a limited extent for genito-urinary disease, psychiatry, and physiotherapy. Some specialties—for example, abnormal maternity, the more specialised forms of ear, nose, and throat work, pædiatrics, ophthalmology, mental diseases, and orthopædics—could not be fully dealt with in every district hospital; but each hospital should attempt to provide in one or more of these special branches a service available to other districts where that particular service has not been developed, or where the number of beds is insufficient for the demand. Such a service is classified as "subregional."

Provision for routine pathological examinations and for clinical pathology would be made at all district hospitals; but the more specialised pathological examinations would be undertaken at one or more regional laboratories; and the rarer specialties would also, of course, be a regional concern. The subcommittee points out that not all regional services would necessarily be centred on a single hospital; and it is conceivable that a district hospital might offer a regional level of service in a particular specialty. The following classification was adopted by the subcommittee:

District level	*Subregional level*	*Regional level*
General Medicine	General Medicine	Plastic Surgery
General Surgery	General Surgery	Thoracic Surgery
Ear, Nose, and Throat	Ear, Nose, and Throat	Certifiable Mental Disease
Ophthalmology	Ophthalmology	Certifiable Mental Deficiency
Physiotherapy	Physiotherapy	Neurosurgery
Pædiatrics	Pædiatrics	Radiotherapy
Psychiatry	Psychiatry	
Maternity (Normal)	Maternity (Abnormal)	
Genito-urinary	Genito-urinary	
Gynæcology	Gynæcology	
Fractures	Neurology	
Dermatology*	Radiotherapy	
Chronic Sick	Mental Deficiency	
	Orthopædics†	

* Certain skin conditions will require facilities at subregional level.

† Linked both with fractures and with rehabilitation centre and plastic surgery.

THE Medical Research Council have reconstituted the Dental Research Committee, whose function it is to advise and assist them in the promotion of scientific investigations in this field. The secretary of the committee is Prof. M. A. Rushton, M.D., department of dental medicine, Guy's Hospital, London, S.E.1.

better not to attempt it. The ampoule should be opened, after swabbing the neck with 70% alcohol applied with sterile swabs, by an assistant whose hands have been scrubbed and dried. It may be held in a sterile towel or piece of sterile lint. The operator must then introduce the needle of the syringe into the ampoule without fouling the mouth.

Other forms of container should be avoided except where absolutely necessary. If a rubber-capped bottle has to be used, the cap should be thoroughly swabbed with 70% alcohol or tincture of iodine and held in a sterile towel by the assistant. The bottle should be returned to the central sterilising depot after use each day.

The intrathecal injection of antibiotics such as penicillin and streptomycin demands the same high standard of aseptic technique; and all precautions should be taken to ensure that the solutions themselves are sterile.

REPORTING OF CASES

The general adoption of the measures recommended here would, without doubt, reduce the incidence of "accidental" meningitis but would not close every possible loophole for infection. Further safeguards can be found only if cases are thoroughly investigated as and when they occur and with the employment of specialised bacteriological methods. The Public Health Laboratory Service will willingly coöperate with the hospital pathologist or other officer in carrying out such investigations as are required.

[1] Gratitude is expressed to Sir Hugh Cairns and Prof. Wilson Smith for the help they gave in the preparation of this memorandum.

HOSPITAL CATERING

A COMPARISON WITH ARRANGEMENTS IN AMERICAN HOSPITALS

MARGARET C. BROATCH
DIETETIC ADVISER TO KING EDWARD'S HOSPITAL FUND FOR LONDON

DESPITE the prevailing shortages many steps have been taken in the last few years by hospitals in this country to modernise their catering arrangements on lines recommended by King Edward's Hospital Fund for London. In some cases a large measure of success has been achieved. The old system whereby a single cooked meal at midday supplemented by simple breakfasts and suppers was considered adequate has been largely discarded, menus have been overhauled, and a much more generous basis including three cooked meals a day has come, in these hospitals, to be regarded as essential to the remedial service. Greater use is being made of the service of dietitians, and capable catering officers are much in demand. Progress is of course hampered by the current conditions, and in some quarters there is a failure to appreciate the distance which our hospitals have yet to travel if they are to offer a service commensurate with their achievements in other directions.

A comparison with the arrangements in American and Canadian hospitals indicates that, apart altogether from the well-planned menus and the variety and abundance of the foodstuffs available which allow for more attractive meals, there are two main directions in which American practice is decisively ahead of ours. In the first place, the visitor from this country is at once struck by the much higher status of the catering service. Catering is invariably entrusted to a dietitian who takes full responsibility for the running of her department financially and for the production and service of meals throughout the hospital, and ranks equally with the superintend of nurses and other heads of departments. The allocat of staff is on a much more generous scale than has e been thought necessary or desirable in hospitals o here. The famous New York Hospital, founded in 1 and rebuilt in the early 1930's, is comparable in size one of our greater teaching hospitals. It has 720 be of which 120 are for private patients and 600 in pavili (=wards) providing for semi-private and ordin patients who pay according to their means. Its sched of staff shows no less than 310 positions on the staf the catering department, ranging from dietitians, coo bakers, and butchers down to tray girls, waitresses, pantry maids. Such a ratio will strike the reader austerity Britain as beyond all reason, and indeed is an extreme example among American hospitals. N the less, many examples could be quoted in this cou of the opposite extreme, and it is a fact that in the majority of our hospitals an upward revision of staffing schedules of the catering departments is overd

MENUS

Nor is the higher standard of feeding that results any means entirely a matter of money and of suppl Much more imagination goes into the planning preparation of menus. The menus throughout are planned and varied, and three good meals a day served to all inmates of the hospitals. A point wor of special note is the abundant use of fruits, fruit jui salads, and vegetables, of which there is always a cho The work is more closely supervised by dietitians t is possible in this country, and thus many more unskil workers are trained within the hospital to become skil hands and often to hold key positions. In most of hospitals visited, meals are served to the staff in a cafeteria. This system is becoming increasingly popu since it has been found that a greater choice of fo can be given, which leads to less grumbling and m contentment among the staff.

If under the National Health Service our hospit are to offer food of a range and quality that mode hospital standards require, it will be necessary to see th an ample margin is allowed for an increase in expendit over and above the levels that prevail today. It is equal important to recognise the need for much more imagin tion in the planning and supervision of the food servi both for patients and for staff. How often a suggest innovation in diet is met by the objection that patients would not appreciate it! Only recently th answer was given to a suggestion that coffee should provided, yet many of the present ward population mu drink coffee regularly in teashops, canteens, and railw refreshment rooms.

EQUIPMENT

Secondly, the visitor is struck by the wholly differen standard that prevails in regard to equipment. Ever labour-saving device obtainable is in use not only i the main kitchens but also in the ward kitchens, a of which are equipped with water-boilers, coffee sets toasters, dish-washing machines, and racks for settin trays. Every patient is provided with a tray, the on most commonly used being made of aluminium wit collapsible legs. An outstanding feature in all hospital is the abundance of stainless steel tables and trucks an of refrigerators. A point of particular interest in the mos modern hospitals is the effort which has been made t cut to the minimum the handling of food, and individual dishes are used wherever possible for salads and desserts. Much use is now being made of frozen foods, and in many hospitals deep freeze-chambers are being installed fo storage of these. Many of the frozen fruits and vegetable are cheaper and more satisfactory than canned and hav superseded them. The high standard of equipment

Reconstruction

NEW YORK'S HEALTH INSURANCE PLAN

Sir RONALD DAVISON

LITTLE has yet been said in this country about the adventure in voluntary health insurance and medical group practice recently begun in New York.

After four years' incubation the Health Insurance Plan of Greater New York, known as H.I.P., emerged as an operative service on March 1 last. In the midst of the war that remarkable man, the late Mayor La Guardia, dreamt of this plan and set up an advisory committee to explore the possibilities of "prepaid medical care" for all families in the middle-income and low-income groups in his vast city and its environs. His dream is now becoming a reality and by the end of this year may cover as many as 100,000 people.

Neither the Federal, State, nor City governments are running this ambitious project. It is based on the private coöperation of the "consumers" of medical services, their employers and unions, and the groups of doctors who contract to provide comprehensive services of a high grade. The city government and the town hall no doubt had a good deal to do with its beginnings—if only because they were the first big employers to join—but it has the status of a voluntary non-profit corporation.

CONTRIBUTIONS

At present H.I.P. does not directly enrol either individuals or families; it will take only groups of not less than 25 people who are associated in their employment—e.g., as members of one firm or of one trade-union. Members can, however, bring in their wives and children on certain conditions. Some sort of income limit seems to be intended, round about $5000, but in contracting for a large group *no objection has so far been raised* to some 5% of higher-salaried members. This enables executives and even employers to be included.

Yet H.I.P. is by no means a charitable organisation. The premiums are fairly stiff, and the rates cover costs of administration and overheads as well as purely medical charges. Thus the contribution payable for employees comes to about $29 per annum, including hospital service, for a single member, and about $87 for a family of three or more: the employer pays half, and the other half is deducted from wages.

A novel feature of the scheme is that the cost of the large family is spread over the units of one, two, and three persons. Thus the married wage-earner with eleven children pays no more than the married couple with one. Even so the high rates probably deter some low-paid employees from joining the scheme.

BENEFITS

What do the enrolled groups get for their money under H.I.P.?

The subscriber receives a certificate guaranteeing:

General medical, specialist, surgical, and obstetrical care.
Diagnostic and laboratory procedures.
Preventive health examinations and immunisations.
Visiting nurse service at his home.
Ambulance service from his home to hospital.

Some 1500 doctors were enrolled soon after the scheme began and they are voluntarily organised in groups which "combine the integrated service of a first-class clinic with the personalised atmosphere of private medical practice." Each subscriber may choose his own doctor from among the group, and he may also choose his medical group within reasonable limits of area. Advanced tuberculosis and other chronic illnesses requiring institutional care are excluded from the scheme, together with dental service and cosmetic surgery.

H.I.P. benefits do not specifically include hospital treatment, but the Associated Hospital Service already existed for this and has a joint contract with H.I.P. and the city, so that the insured employees of the city should have comprehensive coverage. A similar arrangement exists for the staff of UNO and of H.I.P. itself.

DOCTORS' REMUNERATION

Under the scheme doctors are paid on the ca system. The open panel plus fee-for-service was reject as being open to abuse by "patients who tend to sh *around demanding unnecessary procedures*" and "doctors who refer patients to specialists unnecessaril

The size of the doctor's capitation fee was difficult fix because data for the assessment of "average utili tion" were woefully inadequate. Neither America n Britain could produce reliable material, and the co mittee of H.I.P. decided, there and then, that one their important side-lines would be to keep records the amount of professional time the care of a coh of insured people would use in a year. In the end th adopted the following provisional assumptions:

(1) That a group of 12½ doctors could meet the need 10,000 persons. This team included specialists for all "heavy" specialties, and about 1400 patients were alloca to each general practitioner.

(2) That this staff could give an average of separate physician services per person per year—five o or hospital visits and two home visits.

(3) That a doctor should have a 40-hour working w with 4 weeks' holiday.

(4) *That the average remuneration of a full-time physic in the group should work out at $10,000 a year.* A doctor also have patients outside his H.I.P. quota, provided needs of the latter are fully met.

In practice it seems that the medical group wit maximum allocation of 10,000 patients receives a g *income of $192,000 a year*, of which 35% should be aside for expenses—such as salaries for auxiliaries, r telephone, &c.—leaving $124,000 to be divided am the doctors.

ORGANISATION OF THE GROUP

Each group is self-selected and self-organised, but expected to be able to offer a comprehensive servi where it is unable to do so, it must procure help fr outside and pay for this help from the group inco According to the H.I.P. contract each group is to con *of the equivalent of 12½ full-time doctors* (to incl 7 general practitioners, 1 pædiatrician, and 1 obstetric gynæcologist). In the original plan the teams were operate from medical centres, and though this conditi has been relaxed for the present, and doctors may w from their own surgeries, each group has an admi strative centre which provides a 24-hour telepho makes appointments, and keeps the records of the wh team. Some of the groups which are already in be are based on hospitals and medical schools.

H.I.P. has established a medical control board *15 members to examine the qualifications* of doctors w wish *to join the scheme and to inspect* premises a equipment.

According to the first analyses of the research a statistics section of H.I.P.[1] over 26,000 people h enrolled in May and over 42,000 by mid-June. Doct gave 6500 consultations in May and over 13,000 in Ju General practitioners were responsible for 62% of the and 30–35% were classified as "preventive."

1. P.E.P. *Planning*, no. 274, p. 163.

THE British Medical Association's Nutrition Committ set up "to consider and report on the problems of *nutriti* in this country including present nutritional *standards*," m on Dec. 1. The members are: Lord *Horder (chairma* Dr. G. F. Buchan, Miss Harriette Chick, D.SC., Prof. S. Cowell, F.R.C.P., Prof. G. P. Crowden, D.SC., Sir Ja Drummond, D.SC., F.R.S., Dr. R. G. Gordon, Dr. Ja Mackintosh, Prof. V. H. Mottram, M.A., Dr. R. Murray Sco Dr. R. E. Smith, Dr. H. M. Sinclair, Dr. Donald Stewa and Dr. J. G. Thwaites; Sir Hugh Lott, Dr. J. B. Mill and Dr. H. Guy Dain, and Dr. J. W. Bone (ex officio). T committee has power to coöpt additional members who names will be published later, and the *Ministry of* Heal has nominated Dr. H. E. Magee to attend the committee observer.

In England Now

Running Commentary by Peripatetic Correspondents

I was first introduced to a simple preventive of ickness by a patient with whom I was condoling the loss of an eye. "Well anyway," he said philo-ically, "I shall never be seasick again." On my her inquiry, he explained that he used to be the ain of a tramp steamer which took pilgrims to Mecca, he had observed that one-eyed passengers (a fairly proportion) were never sick.

thought I would discuss this novel idea with a higher ority, so I asked an ex-surgeon-rear-admiral (tem-ry) what he thought. "Of course it's true," he : and then, lowering his voice, "it was the only g that enabled me to hold down my job in the war." ppeared that he was ill if he went on the lake in nt's Park, and it doesn't look well for an admiral be sick in fine weather. Besides, it's very difficult vomit with dignity wearing a cap, and it seems that al officers mustn't take them off on duty. Anyhow n he couldn't escape going on the water (which for-tely was seldom) he developed a nasty stye so that wore an eye shade, with the happiest results. "To absolutely sure," he concluded, "stuff cotton-wool the opposite ear." To my astonished question , he murmured vaguely. "Oh, you know, semi-ular canals and things."

If these personal experiences are confirmed it will be ible to overcome a most distressing malady by the plest means. Nor is this without a military value. D-day, instead of fiddling about with hyoscine ctions, the invaders could have jumped on the ches tearing off red eye shades with one hand and ling out blue ear plugs with the other. Perhaps the rmans would have thought this was the secret weapon last and would have capitulated without resistance.

* * *

It was in the City of Loving Brothers that I came across autiful example of filial and paternal understanding affection. Both father and son were well-known skilful surgeons. The father had gained his skill the harder school of experience, the son had been ed in a world-famous clinic. I was a guest and the was booked to perform a cholecystectomy. The nt was anæsthetised and the operation-area pre-d. The father, dressed up to assist at the operation, all-attentive but unusually quiet. Suddenly the son, ing his father's thoughts and wishes, said, "I would my father to do this operation" and moved round the other side of the patient. The father, obviously tified, promptly went to work and removed an med gall-bladder and extracted stones from the mon duct in a masterly manner.

* * *

I don't suppose many people owe their lives to having ; my bearer does.

ws of the disturbances in the Punjab was scanty in hmir, and most of the many rumours appeared to be erations. Military personnel were forbidden to vel on trains going through the disturbed area, but I had to get back to Delhi, and so put on mufti at walpindi. All went well until we reached Lahore, north of the trouble. Here all the Muslims got off train, which was reduced from nine coaches to two—ving ample accommodation for the three travellers t—another European, my bearer, and myself. We ssed the Indo-Pakistan border without incident, and en the train was besieged by thousands of non-Muslim fugees. More coaches were added but every seat and ery square inch of the floor, running-boards, and roof s occupied by a mass of humanity complete with ndles, bicycles, pots and pans, innumerable children, d all the paraphernalia of the East. As we crawled t 10 miles an hour towards Delhi I breathed a sigh of lief, closed the wooden shutters on the windows, and ttled down for a sleep, confident that after all the mours were exaggerated.

I was woken by banging on the carriage doors, and ening the shutters saw that the train had been stopped n open country by a band of Sikhs armed with swords, home-made spears, and villainous little axes mounted on the end of long bamboo poles. They were searching the train for Muslims, whose fate could not be in doubt. They swarmed into the compartment, pulled the luggage from under the seats in case someone was hiding there, and showed the greatest interest in my bearer who was lying on the top berth. "Mussalman, Mussalman," they cried and began to drag him from the train. I protested that he was a Christian, and showed them, tattooed on his forearm, a naked lady. They were somewhat sceptical of this being a Christian emblem, and continued to shout "Mussalman." A large crowd had now collected round the carriage and my wretched bearer was trembling with fear. "He's a Christian," I insisted. "If you think he's a Muslim go into the lavatory and see for yourselves. He's not been circumcised." I waited outside, sick at the thought that perhaps he had not told me the truth and that he really was circumcised. The examination seemed interminable, and then came a loud laugh. The Sikhs emerged, grinning from ear to ear. "I don't know, Sahib, whether he's been circumcised or not," said one of them, "but he's certainly got V.D."

My bearer is still in hospital. It's taking a lot of penicillin to cure him, but now that the gross infection has subsided it is clear that he was somewhat inadequately circumcised in childhood.

* * *

A team of industrial psychiatrists had spent several days in an iron and steel works. Their investigations and analyses had gone smoothly except for one puzzling incident in the dispatch department. Here some twenty elderly workmen, each provided with a two-wheeled trolley, carried sacks of nuts and bolts down an incline to the edge of a canal where they tipped their load into a barge. Nineteen of the men pushed their trolley in front of them but the twentieth pulled his behind him, and this required additional manœuvring.

It was clear that this man was less efficient than his mates, but what puzzled the psychiatrists was why he pulled his trolley instead of pushing it. They spent the morning watching Sam, for that was the name of the black sheep, but came to no satisfactory conclusions, and brought the matter up at lunch in the director's dining-room. The works manager treated the whole matter with ridicule; he was a hard-headed Scot and had little time for these new-fangled investigators. Having listened with scorn to a variety of theories he said, "Och, why don't ye ask the mon why he pulls yon trolley and be done wi' it?"

Such horse-sense was irrefutable, and after lunch the party returned to the dispatch bank. The works manager was wasting no time and beckoned to Sam. "Now Sam," he said, "these gentlemen want to know why ye pull yon trolley and nay push it like t'other lads." Sam seemed quite nonplussed by the question and somewhat embarrassed. He stood on one leg and then on the other. He removed his greasy cap and fumbled it in his hands. "I don't rightly know," he replied in a raw Midland accent, "but I reckon it's because I'm sick of the sight of the bloody thing."

* * *

"Don't be worried," I told my wife, "but I've had another bleed from the old ulcer. I haven't been sick or anything yet, but we old chronics get very knowing, and there's one sign that is quite unmistakable after a time or two—the taste of the wind you bring up when you've been bleeding. Sounds rather disgusting, but I didn't want to startle you by vomiting a lot of blood in the night when you weren't prepared for it. If I can have a jerry under the bed and a bath-towel handy I shan't make any mess—in fact I needn't wake you up at all. I shall stay in bed in the morning, of course, but don't let's have any alarm or despondency this time. . . . What did you say? Couldn't it be that underdone liver we had for lunch? Good gracious, perhaps it is."

It was.

* * *

He was an experienced and skilful surgeon but absent-minded, especially when flustered. One day he was to perform a very minor operation which among certain races constitutes a religious rite. Arriving late for the appointment, he was met by the mother holding the victim in her arms. Patting the infant on the head, he said "What a delightful baby!", and then with his best smile, "Is it a boy or a girl?"

Reconstruction

NEW YORK'S HEALTH INSURANCE PLAN

Sir RONALD DAVISON

LITTLE has yet been said in this country about the adventure in voluntary health insurance and medical group practice recently begun in New York.

After four years' incubation the Health Insurance Plan of Greater New York, known as H.I.P., emerged as an operative service on March 1 last. In the midst of the war that remarkable man, the late Mayor La Guardia, dreamt of this plan and set up an advisory committee to explore the possibilities of "prepaid medical care" for all families in the middle-income and low-income groups in his vast city and its environs. His dream is now becoming a reality and by the end of this year may cover as many as 100,000 people.

Neither the Federal, State, nor City governments are running this ambitious project. It is based on the private coöperation of the "consumers" of medical services, their employers and unions, and the groups of doctors who contract to provide comprehensive services of a high grade. The city government and the town hall no doubt had a good deal to do with its beginnings—if only because they were the first big employers to join—but it has the status of a voluntary non-profit corporation.

CONTRIBUTIONS

At present H.I.P. does not directly enrol either individuals or families; it will take only groups of not less than 25 people who are associated in their employment—e.g., as members of one firm or of one trade-union. Members can, however, bring in their wives and children on certain conditions. Some sort of income limit seems to be intended, round about $5000, but in contracting for a large group no objection has so far been raised to some 5% of higher-salaried members. This enables executives and even employers to be included.

Yet H.I.P. is by no means a charitable organisation. The premiums are fairly stiff, and the rates cover costs of administration and overheads as well as purely medical charges. Thus the contribution payable for employees comes to about $29 per annum, including hospital service, for a single member, and about $87 for a family of three or more: the employer pays half, and the other half is deducted from wages.

A novel feature of the scheme is that the cost of the large family is spread over the units of one, two, and three persons. Thus the married wage-earner with eleven children pays no more than the married couple with one. Even so the high rates probably deter some low-paid employees from joining the scheme.

BENEFITS

What do the enrolled groups get for their money under H.I.P.?

The subscriber receives a certificate guaranteeing:

General medical, specialist, surgical, and obstetrical care.

Diagnostic and laboratory procedures.

Preventive health examinations and immunisations.

Visiting nurse service at his home.

Ambulance service from his home to hospital.

Some 1500 doctors were enrolled soon after the scheme began and they are voluntarily organised in groups which "combine the integrated service of a first-class clinic with the personalised atmosphere of private medical practice." Each subscriber may choose his own doctor from among the group, and he may also choose his medical group within reasonable limits of area. Advanced tuberculosis and other chronic illnesses requiring institutional care are excluded from the scheme, together with dental service and cosmetic surgery.

H.I.P. benefits do not specifically include hospital treatment, but the Associated Hospital Service already existed for this and has a joint contract with H.I.P. and the city, so that the insured employees of the city should have comprehensive coverage. A similar arrangement exists for the staff of UNO and of H.I.P. itself.

DOCTORS' REMUNERATION

Under the scheme doctors are paid on the capitat system. The open panel plus fee-for-service was reject as being open to abuse by "patients who tend to sh around demanding unnecessary procedures" and "doctors who refer patients to specialists unnecessarily

The size of the doctor's capitation fee was difficult fix because data for the assessment of "average utili tion" were woefully inadequate. Neither America r Britain could produce reliable material, and the co mittee of H.I.P. decided, there and then, that one their important side-lines would be to keep records the amount of professional time the care of a coh of insured people would use in a year. In the end th adopted the following provisional assumptions:

(1) That a group of 12½ *doctors could meet the needs* 10,000 persons. This team included specialists for all "heavy" specialties, and about 1400 patients were alloca to each general practitioner.

(2) That this staff could give an average of separate physician services per person per year—five o or hospital visits and two home visits.

(3) That a doctor should have a 40-hour working w with 4 weeks' holiday.

(4) *That the average remuneration of a full-time phys in the group should work out at $10,000 a year.* A doctor also have patients outside his H.I.P. quota, provided needs of the latter are fully met.

In practice it seems that the medical group with maximum allocation of 10,000 patients receives a g income of $192,000 a year, of which 35% should be aside for expenses—such as salaries for auxiliaries, re telephone, &c.—leaving $124,000 to be divided am the doctors.

ORGANISATION OF THE GROUP

Each group is self-selected and self-organised, but expected to be able to offer a comprehensive servi where it is unable to do so, it must procure help fr outside and pay for this help from the group inco *According to the H.I.P. contract each group is to con* of the equivalent of 12½ full-time doctors (to incl 7 general practitioners, 1 pædiatrician, and 1 obstetric gynæcologist). In the original plan the teams were operate from medical centres, and though this condit has been relaxed for the present, and doctors may w from their own surgeries, each group has an admi strative centre which provides a 24-hour telepho makes appointments, and keeps the records of the wh team. Some of the groups which are already in be are based on hospitals and medical schools.

H.I.P. has established a medical control board 15 members to examine the qualifications of doctors w wish to join the scheme and to inspect premises a equipment.

According to the first analyses of the research a statistics section of H.I.P.[1] over 26,000 people h enrolled in May and over 42,000 by mid-June. Doct gave 6500 consultations in May and over 13,000 in Ju General practitioners were responsible for 62% of the and 30–35% were classified as "preventive."

CHILBLAINS

SIR,—In your annotation of Nov. 29 you referred to the fact that chilblains are almost unknown in America. I can confirm this from my own experience. I suffer moderately from this condition every winter, but when I spent two years in New England I was completely free, although one winter was very severe with considerable spells of sub-zero temperatures.

I am sure that chilblain sufferers in this country would benefit from better-heated houses as you suggest, but I believe this would be the result not so much of *warmer* as of *drier* surroundings. Chilblains, in my view, occur in damp chilly conditions rather than in really cold weather. Personally, I suffered less than usual last winter in spite of very inadequate heating. Temperatures between 30° and 39°F with wet or foggy weather are the worst. When the temperature drops sufficiently below freezing-point, with hard frost or dry snow, there is insufficient moisture to produce the condition.

I have no particular theories as to how dampness is concerned in the production of chilblains. Probably it prolongs the state of chill, since it requires more body heat to warm up socks, shoes, and gloves if they are damp and cold than if they are dry and cold. Dry snow can be readily kicked or shaken off boots and gloves, while wet snow cannot. I believe that the freedom from this complaint in America is due chiefly to their dry winter climate, assisted by properly heated houses and perhaps also by abundant sunshine.

I should be interested to know if your readers confirm my experience of comparative freedom last winter.

London, N.W.3. ROSEMARY PRITCHARD.

TUBOCURARINE IN TETANUS

SIR,—The letter of Dr. Gordon Sears (Nov. 29) describing a case of tetanus treated with tubocurarine prompts me to report briefly two cases which have occurred in this district this year.

CASE 1.—A girl of 9 years had pierced her finger with a thorn. Symptoms were severe from their onset some days later, and the child was very ill when admitted to hospital. The treatment followed the usual lines in regard to serum re penicillin, administration of fluid and paraldehyde; taken tubocurarine was given in doses of 5 mg. at the sta onset, spasms, which were very severe and perforated gastric 1-minute intervals, were de Some of the patients, frequency by the curare also of pain in the shoulder, and drug might be Mc cue that the diaphragm was involved; depressing effe ed that none of the patients in the series was though by Hamburger and McNeil had this symptom. were gi he nature of the epidemic was realised, diagnosis mus made without difficulty, and one could confidently se sure the anxious patient that the pain would be gone in 24–48 hours. Only a minority relapsed after the initial pain had disappeared. Cases of benign lymphocytic meningitis were seen at the same time, but such cases occurred among troops in other districts where no epidemic of Bornholm disease prevailed.

Lambeth Hospital, London, S.E.11. A. L. WYMAN.

TREATMENT OF BOILS

SIR,—The prevalence of boils and carbuncles in general practice, which was noted by Dr. Gottlieb in your issue of Nov. 29, will surely be confirmed by most general practitioners. I noted a similar increased incidence in the autumn of last year. May I suggest that the reason is the combination of lessened blood-supply and increased humidity of the skin, due to the damp cold air of autumn? Pathogenic staphylococci are ever present on the human skin, awaiting an opportunity to pierce the body's defences.

The general practitioner, in applying penicillin treatment, has to follow the dosage schemes issued by various research-workers. Of late one has been somewhat bewildered by rapidly changing opinions on this subject. For boils, carbuncles, and septic fingers, I have used 100,000 units twice daily, then 200,000 units once daily, and finally 500,000 units once daily. With all these dosages seemingly complete cures have been obtained. One of my patients, a girl of 17, with furunculosis of the knee, relapsed after a 3-day course as a hospital out-patient, and again after a 7-day course. On both of these

Letters to the Editor

PATHOLOGY IN THE NATIONAL HEALTH SERVICE

SIR,—It would be most helpful if official information could be given about the proposals for developing the pathology service under the new National Health Service.

From several sources unofficial information has lately come to hand that the hospital pathology service is going to be organised separately from the rest of the professional hospital services, apparently along the lines of the E.M.S. pathology services. We do not wish to belittle the great work done by this Emergency Medical Service and those who have worked in it. Nevertheless, justifiable criticisms have been brought against some aspects of it.

Clinicians and pathologists with whom we have discussed this subject, and who have given it thought, are strongly of the opinion that such an arrangement would be a great mistake and not at all conducive to the realisation of the best type of hospital medical practice. We think we are aware of the arguments likely to be put forward in favour of a separate pathology service. There is not one which approaches in importance those against such a service. For the best type of liaison between clinicians and pathologists it is essential for the latter to be an integral part of the hospital's service and staff. It is important that administratively they should be on the same footing as all other hospital medical staff. A full meeting of the members of the Royal College of Physicians on Nov. 27 last agreed to this principle without dissent.

We understand that the development of the new pathology service may already be far advanced in some regions. It is difficult to understand why we were not informed of the new proposals long ago. May we hope for full information quickly, and a realisation on the part of those organising the new service that all pathologists and clinicians are very much concerned with it and should be consulted before any arrangements reach finality?

THE SYMPTOMS OF CERVICAL-ROOT IRRITATION

SIR,—Dr. Russell Brain and Mr. D. W. C. Northfield, addressing the physical-medicine section of the Royal Society of Medicine on Nov. 12, made a valuable contribution to several branches of medicine by their lucid discussion of cervical-root lesions.

Though the distribution of pain in the areas supplied by cutaneous nerves is well known, it is not adequately appreciated that irritation of cervical nerve-roots will also produce pain over a much greater area and depth, even far removed from the cutaneous nerve-supply, because of sensation carried in the nerves supplying muscles. Irritation of C7 nerve-root causes pain attributed to a small area of skin on the arm, forearm, and hand, and a larger volume of muscles, fasciæ, ligaments, periosteum, and other structures in both the trunk and the limb. Fibres of any of the following muscles may be concerned:

(1) *Via the posterior primary division:* splenius cervicis, semispinales, interspinales, and intertransversales.

(2) *Via the anterior primary division:* scaleni medius and posterior, latissimus dorsi, serratus anterior, pectoralis major, triceps, anconeus, coracobrachialis, extensors of the digits, extensor carpi ulnaris, flexor digitorum sublimis, and (possibly) longus cervicis, and extensores carpi radialis longus et brevis.

Opinions differ among anatomists about the detailed nerve-supply of all these muscles, whose degree of innervation by C7 varies from one muscle to another. Some of these muscles, besides receiving nerve-fibres from C7 and other cervical roots, also acquire thoracic innervation. Further, as Dr. Brain pointed out, additional variations exist in the case of pre- and post-fixed plexuses. Though the details may vary from case to case, the general anatomical arrangement explains why irritation of t posterior root of C7 causes a known area of skin and wider and less determinate expanse of muscle and oth deep structures to become the apparent sites of pai why damage to the anterior root is followed by wasti which, difficult to assess in any local group of muscl may be appreciable in the aggregate; and why t symptoms are so widespread and the peripheral sig so few. It is the overlapping of such widely distribut fibres with those from other roots that produces a clini picture which is confusing if the anatomy is not ke in mind.

Pain in the neck, arm, and trunk is very comm In patients with such pain careful radiography (includi oblique views) of the cervical spine often reveals a lesi There may be only an irregularity of outline of one int vertebral joint, near which one root may have be injured; or a more extensive lesion may be seen. Norm radiograms, on the other hand, do not preclude a lo lesion. It has been stated repeatedly that abnormalities are found in patients presenting symptoms referable to the cervical spine; but aga this I advance the following facts:

(1) The cervical spine is rarely radiographed unless patient has symptoms.

(2) The symptoms are not correlated with the abnormalit found; perhaps more often than is done at present some the symptoms are referable on an anatomical basis to cervical spine.

(3) Instead of such a reference many such syndromes termed "functional" or "neurotic." Yet no reasona improvement in the symptoms follows the well recogni methods of dealing with neurosis

(4) The pain is usually eased temporarily by analges which are of little value in anxiety states, unless any anx which may be present is the result, not the cause, of symptoms—i.e., relief of the organic symptoms relieves anxiety.

Therefore our views about what constitutes normal or unrelated radiographic findings should be reconsider

In the more severe phases pain in the chest and a has simulated that of cardiac ischæmia, particul when an exertion which alters the alignment of t vertebræ is undertaken. The carrying of a hea bulky object on one side—e.g., a shopping basket rather than two smaller ones, one in each hand, m necessitate a contralateral flexion of the lumbar a thoracic vertebræ with ipsilateral flexion of the cervi to maintain balance and keep the eyes horizontal. B there are countless other combinations of attitudes a angles between the vertebræ in lifting, carrying, readju ing, and lowering weights. On the whole, cervic root pain from a skeletal lesion follows the *type* movement, cardiac angina its *amount*.

Pain at night is experienced through incorrect adju ment or depth of pillows or through rotation and late flexion of the neck in sleep. Further, in the state betwe sleeping and waking the patient may stiffen up, there forcibly extending the neck.

Sneezing and coughing both cause jolting. Sympto may occasionally be prevented by flexing the ne and opening the mouth so that the chin rests on t chest, and raising and adducting the shoulders. Th combined action, besides supporting and stabilising t lower part of the neck, helps to relax the rhomboid levatores scapulæ, and some other muscles attached t the vertebræ. It also allows maximal separation of t bones at the intervertebral foramina, where the nerv might otherwise be compressed by the sudden jolt.

If a definite local obstruction can be demonstrated b myelography, this, together with the signs and oth radiographic findings, should make the diagnosis eas Why, then, is it possible for symptoms to exist withou any definite evidence of obstruction? I suggest th many of the features of the common type of lesion—that without evidence of damage to the cord—can b explained by conditions in the intervertebral foramin Prolapse of the disc allows the approximation of th adjoining vertebræ now supported only by lax muscl and ligaments. Further, the tone of some muscles wi be lost owing to damage to their nerve-supply not onl

Mr. LINSTEAD pointed out that, apart from medicines scribed under the National Health Insurance Act, the medicines prescribed today were proprietary medicines and would attract the 33⅓% tax. The old medicine stamp duty, he added, did not apply to medicines sent to the chemist to be sent out with a medical prescription.

The amendment was negatived by 278 votes to 131.

Medical Practitioners and Pharmacists Bill

This Bill, which has already passed through all its stages in the House of Lords, was given a second reading in the House of Commons on Dec. 5. Mr. BEVAN in proposing the motion stressed the necessity of getting the Bill passed into law by the end of the year. for doctors on the temporary register would otherwise be unable to continue to practise after Dec. 31. When the temporary register closed there would be, he thought, about 3500 doctors, but it was estimated that only 1500 to would wish to remain. There would also be a further Polish doctors brought here under the Polish Resettlement Scheme. Mr. Bevan admitted that the closing date, arbitrarily fixed as Aug. 4, might give rise to cases of individual hardship, but it could not be avoided. In the committee stage he would introduce an amendment to enable doctors attached to our establishments abroad to practise in this country.

Mr. WALTER ELLIOT welcomed the Bill as a measure of relaxation instead of restriction, and promised that the Opposition would afford every facility to secure its speedy passage into law. Mr. SOMERVILLE HASTINGS also welcomed the Bill, which. he added, it was an open secret, had arisen at the suggestion of the doctors themselves. He was uneasy about clause 8 which permitted foreign postgraduate students to undertake medical work in our hospitals. He suggested that the words "demonstration and instruction" should be substituted for "employment," and that such appointments should be limited to teaching hospitals where supervision was more complete.

Colonel M. STODDART-SCOTT said it appeared that the General Medical Council would undertake some sort of screening, and would decide from whom registration should be withheld. Would this decision, he asked, be made purely upon medical qualifications or service, or in what way? He welcomed the provision allowing the doctor right of appeal to the Privy Council from a G.M.C. decision. A British doctor under the National Health Service Act would not have the same privilege. Sir HENRY MORRIS-JONES suggested that there should be some form of examination, as well as a probationary period, before the new entrants were admitted.

Mr. H. LINSTEAD regretted that it had not been possible for the medical profession to do as the pharmaceutical profession had done, and omit the proviso of the closing date.

Mr. BEVAN in his reply said he was an enthusiast for providing postgraduate facilities in this country for students from abroad. It was a grief to him that students from the Colonies sometimes went elsewhere because we had not facilities for them in London. Therefore he deprecated Mr. Hastings's cold douche on the Bill's provision for the registration of these students. The Bill was only regularising a practice which already existed, and, as the students would be in hospital under supervision, the patients would be protected. The right of appeal to the Privy Council given in this Bill was not inconsistent with his views on the National Health Service. Here it was a question of professional qualifications—an entirely different matter from whether a person was giving suitable service or not. It was impossible for him to reconsider the closing date, for the Bill was an agreed measure, and it would be a breach of faith.

QUESTION TIME

Doctors in the Services

Replying to questions, the Services Ministers stated that the present ratio of medical officers to the total strength of the Navy is 3·25 per 1000; of the Army 3·5 per 1000. of the R.A.F. 3·1 per 1000.

Number of Medical and Dental Students

In reply to a question, Sir STAFFORD CRIPPS stated that the numbers of full-time medical (including dental) students attending university institutions in Great Britain were as follows:

	Men	Women	Total
Autumn term, 1947	12,389	3175	15,564
Academic year, 1938–39 ..	11,623	2013	13,636

Calorie Value of Potatoes

Mr. HENRY STRAUSS asked the Minister of Food what calorie value per oz. of potatoes he had assumed in estimating the loss through rationing at 70 calories a day.—Mr. J. STRACHEY replied: Sixteen.

Industrial Health Research Board

Mr. F. J. ERROLL asked the Lord President of the Council how long the post of secretary to the Industrial Health Research Board had been vacant; and what steps were being taken to fill it.—Mr. H. MORRISON replied: The board is part of the organisation of the Medical Research Council, and the secretarial duties are performed by members of the council's headquarters staff, one of whom has been giving whole time to the work since the board's previous secretary left at the end of September, 1946. The detailed work of the board has recently been divided among four committees dealing with special branches of occupational health and each of these has its own scientific secretary.

Obituary

CHARLES BOLTON

C.B.E., M.D., D.SC. LOND., F.R.C.P., F.R.S.

Dr. Charles Bolton, consulting physician to University College Hospital, died in London on Dec. 6 at the age of 74.

Born at Whitby, he began his medical work at the age of 16 as a pupil of a general practitioner who was a friend of his family. He especially valued this early training. for he believed that the recognition of physical signs was one of the most important and difficult parts of a medical education, and that skill in observation is most easily acquired before the mind has become burdened with much factual knowledge. Such store did he set on this form of instruction that even as a senior physician he continued to take many junior classes in clinical medicine.

Press Portrait Bureau

When he began his more formal education at University College, at which his elder brother, Joseph Shaw Bolton, had preceded him. his early experience proved of great value, and he carried off many of the medals, exhibitions. and scholarships. After qualifying in 1896, he held house-appointments under Rickman Godlee and F. T. Roberts. before becoming resident medical officer at the Evelina Hospital, and later assistant medical officer at the Eastern Fever Hospital at Homerton. It was here that his interest in medical research was aroused, and together with William Bulloch of the London Hospital he studied the origin of the agglutinins in the serum of an infant whose mother had contracted typhoid fever.

In 1900 he returned to University College Hospital. where he held the difficult office of resident medical officer during the building of the present hospital. In 1903 he was awarded a research scholarship of the Grocer's Company, and in the same year he was appointed to the staff of the Queen's Hospital for Children. Two years later he became assistant physician to U.C.H., occasions the knee had cleared up completely. I did not attempt a third course, but have used staphylococcal vaccine, with success. In using sulphathiazole, I have been disappointed several times after prescribing 20 g. in 3 days for patients with boils.

In considering the reasons for failure or relapse with penicillin or sulphonamide treatment, adequacy of dosage and proper spacing of injections are of course important. (From the general practitioner's point of view it would be a great help if single daily doses of aqueous penicillin were sanctioned by the pundits.) But it may be that staphylococci in poorly vascularised regions—and especially on the skin—get only enough contact with penicillin to enable them to develop a resistance. Instead of relying on penicillin alone for controlling boils, &c., we should perhaps return to broader lines of treatment, such as the use of vaccines, skin sterilisation, and reduction of carbohydrates in diet.

Dr. Mary Barber, writing in the *British Medical Journal* of Nov. 29, described penicillin-resistant strains of staphylococci which may or may not have acquired the resistance after penicillin treatment. Where resistant organisms occur and clinical response is unsatisfactory, dosage and spacing must be revised. In any case, vaccines prepared from penicillin-resistant strains might be of help in the treatment of recurrent infections.

Hornchurch, Essex. I. H. J. BOURNE.

ADVISERS TO THE BOARDS

SIR,—Your leading article of Dec. 6 is certainly timely, as the development of a full-time professional bureaucracy in each region would be most regrettable.

Perhaps the situation as regards psychiatry has arisen following the relative neglect of this subject by the universities. Thus, in London there are professors of medicine, surgery, and pathology at all the teaching hospitals, but only one professor of psychiatry for the whole territory, with two additional professors in the provinces. Scotland, as is not unusual, appears to be better served in this connexion.

If the community can afford a full-time "top-grade" psychiatrist in each region, surely this individual should be a professor of psychiatry at the main teaching hospital, whence his services would be available to coöperate with the regional medical advisory committees advocated in your leading article, rather than another administrator divorced from medical teaching and research.

Horsham, Sussex. T. M. LING.

Public Health

Poliomyelitis and Polioencephalitis

THE more rapid decline in notifications mentioned last week has been maintained. In the week ended Nov. 29 notifications of poliomyelitis were 103 (142) and of polioencephalitis 3 (3). Figures in parentheses are those for the week ended Nov. 22. It has been suggested that in epidemics original notifications overstate incidence. This is confirmed by the following figures for poliomyelitis supplied by the General Register Office:

	Notifications	
Quarter	*Original*	*Corrected*
June	268 ..	244
September	6192 ..	5077

Infectious Disease in England and Wales

WEEK ENDED NOV. 29

Notifications.—Smallpox, 0; scarlet fever, 1765; whooping-cough, 1513; diphtheria, 216; paratyphoid, 18; typhoid, 8; measles (excluding rubella), 2772; pneumonia (primary or influenzal), 567; cerebrospinal fever, 44; poliomyelitis, 103; polioencephalitis, 3; encephalitis lethargica, 0; dysentery, 77; puerperal pyrexia, 134; ophthalmia neonatorum, 51. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from whooping-cough, 1 (0) from enteric fever, 1 (0) from measles, 1 (0) from scarlet fever, 3 (0) from diphtheria, 61 (4) from diarrhœa and enteritis under two years, and 18 (1) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 189 (corresponding to a rate of 23 per thousand total births), including 27 in London.

Parliament

FROM THE PRESS GALLERY

Purchase-tax on Drugs

DURING the committee stage of the Finance Bill in the House of Commons on Dec. 2, Mr. SELWYN LLOYD moved an amendment to clause 5 to exclude manufactured or prepared drugs and medicines from the increase in purchase-tax. He said that at the moment drugs and medicines were subject to a tax of a sixth, which was now to become a third, of the wholesale value of the goods. Was it not rather sadistic that the Government should double the tax on such simple remedies as iodine, quinine, and the simple forms of nerve tonic? Almost all the ingredients of the common cough mixtures, certain of the drugs for relieving pain, and many of the simpler medicines would be subject to the increased tax. 'Vaseline' bought in a 4 oz. tin was free of tax, but in smaller quantities it was not. This imposition constituted an additional tax on sickness and on things which might prevent minor ailments from becoming more serious. If the result was to turn minor ailments into hospital cases it might easily defeat its purpose. The Government themselves were large purchasers of drugs, he continued, and the financial aspect could not therefore be important.

Sir HENRY MORRIS-JONES had never understood why drugs and medicines were subject to purchase-tax at all. In the overwhelming majority of cases they were a necessity. He urged that special consideration should be given to drugs which were preventives and sedatives.

Mr. F. J. ERROLL held the tax discriminated unfairly between different types of diseases, and added to the difficulties of the chronic sick and the aged and infirm. While there was an amazing list of drugs and medicines on which the new tax was to be levied, there were notable exemptions such as penicillin, the sulphonamide group, vaccines, and morphine. Thus we taxed the cure of toxic goitre and malaria, but left the cure of pneumonia and gonorrhœa free. There was the further point that the dispensing practitioner, particularly when he was also a panel doctor, received a fixed rate for the medicines he supplied, and any increase in the purchase-tax on their ingredients must be entirely borne by him.

Mr. H. LINSTEAD, in supporting the amendment, asked the Chancellor of the Exchequer to have a look at the whole operation of the purchase-tax as it affected medicine. When this matter was last discussed the then chancellor indicated that he could not afford the loss of revenue—something like £9 million—which the remission of the tax would entail. But it was no longer a case of balancing the budget but of curtailing expenditure on non-essentials. Nobody could maintain that drugs were non-essentials, but the Chancellor might have a good deal of sympathy if he imposed additional taxation on patent medicines.

Sir STAFFORD CRIPPS said that for some time discussions had been going on with the Ministry of Health on the question of getting the list of drugs in the exemption order extended and put on a sounder basis. He agreed that its present basis did not seem to be wholly logical. Before next April he hoped it would be re-examined with a view to excluding drugs which were of real importance. He would remind the House that prescribed medicines did not attract the tax, though some drugs in the medicine might be taxed, but looking at the proportion of the drugs and the cost, compared to the final article, it was clear that the incidence was not heavy. Most of the receipts from this tax were a substitution for the old stamp duty on patent medicines. He could not believe that the taking of patent medicines without the advice of a doctor was a good way of dealing with the health of the population. While he could not accept the amendment he proposed to look into the matter before next April to see whether a more logical system of exemptions could be devised. They would be much helped by the fact that the new National Health Service Act would be coming into operation, and they would have the assistance of the Ministry of Health, who would be large users of drugs in the hospitals and elsewhere.

Notes and News

THE DON'S WARNING

DOCTORS who read Nigel Balchin's book, *Mine Own Execu-* r, can hardly fail to be impressed by the advice a deaf spiritless don gives Milne in the first chapter. Milne, who taken a first in physiology, anatomy, and chemistry, to train forthwith as a psycho-analyst. "'Well,' says don, 'there's no doubt you'd have to qualify first. No at all. It gives you'—he waved a hand—'all the back- d.'" Milne and Mr. Balchin hardly keep their patience one so remote and ineffectual; but the rest of the book to vindicate him handsomely. If Milne had had "all ckground" would he really have thought analysis was ng for Adam Lucian? It seems doubtful. Mr. Balchin ers he made his blunder later, when he allowed Lucian tpone a critical session and go home to murder his Milne's hunch that all was not well was obscured by ache: very human, but it led to the agonising death person of remarkable quality, and the suicide of Lucian f. The strictures of the coroner are lightly wafted off e of Milne's medical colleagues, who cleverly claims part e responsibility. The lesson, for Mr. Balchin, seems to t though we all make mistakes, the unqualified analyst, er good—and Milne, his fellow-workers all agree, is good—will get no quarter when he blunders. For s, and perhaps especially for psychotherapists, the is rather that a medical training, whatever its faults, one to deal humbly and cautiously with a psychosis.

film, now showing in London, of this very interesting well-written book, is presented by Alexander Korda and ed by A. Kimmins. The script is written by Balchin, it follows the text so faithfully (though the scene with don is omitted) that it becomes a kind of documentary e book. There are some good paralysing shots at the when Milne is climbing a fireman's ladder to get to n, solitary on the parapet of the great building; but e whole the photography is competent without being g, and the same might be said of the cast.

DENTAL CARIES IN SWEDEN

Swedish Royal Medical Board is instigating investi- s into the prophylaxis of dental caries. Completely y teeth are now found in only 3 out of every 1000 h children between 7 and 15 years and in only 1 per young adults (average age 20). On the other hand, the 870 patients in the Lund hospital for ineducable l defectives 31 have perfect teeth.

CENSORSHIP OF PATIENTS' READING

question whether some form of censorship of the read by patients in hospital is desirable was discussed recent meeting of the Guild of Hospital Librarians with Buchanan in the chair. Miss Southernden, the member the Croydon Public Library staff assigned to the work in l and mental hospitals, maintained the principle, lly accepted by public librarians, that the provision of for patients in hospital is an extension of the home- service, so they would be no more subject to restrictions are ordinary readers. The suggestion that patients d of being debarred in any way in their reading should e special assistance from the librarian to guide their e of books received general support. Mrs. Mackenzie, the point of view of a lecturer in psychology, objected it was not possible to discuss the subject in relation to nts as a body. It was necessary to study the reactions the individual. The librarian can assess projection and ation. Dr. L. Fairfield, a senior medical officer of the don County Council, supported the objection to any form censorship with the one exception that patients suffering cancer should not be allowed to read books referring to t disease. Tuberculous and neurotic patients are not cted by books bearing on those subjects, and in fact the ription of their own conditions may in some cases be ful to patients. Maternity patients should not have fears d by books about abnormalities in childbirth but t well have any such ideas dissipated by good books t motherhood and child life. One type of reading to be ded by the sick is the desultory reading which leaves no ession. She condemned "the ridiculously overplayed ms of bibliotherapy" prevalent in the United States.

University of Cambridge

On Dec. 6 the regent house resolved that from the beginning of the next academic year women shall be admitted to matriculation and degrees on the same terms as men. They will be eligible for appointment to all university offices except those of proctor and esquire bedell. Girton and Newnham, instead of being "recognised institutions," will be colleges of the university.

University of London

Dr. N. F. Maclagan has been appointed to the chair of chemical pathology at the Westminster Hospital medical school.

Dr. Maclagan, who is 42 years of age, was educated at University College School and University College, where he graduated B.SC. with first-class honours in 1925. In 1926 he was appointed to a research scholarship in the biochemical department of Middlesex Hospital, where the following year he began his medical training, while continuing to act as part-time assistant in the biochemical department. He graduated M.B. in 1932, and after holding a house-appointment under Dr. G. E. S. Ward, became assistant in chemical pathology to the Courtauld Institute of biochemistry, where he later continued his researches on gastric secretion as a whole-time worker of the Medical Research Council. In 1935 he was appointed biochemist to the Westminster Hospital, but from 1939 to 1945 he was on leave of absence as pathologist at an E.M.S. sector pathological laboratory. In 1946 he returned to the Westminster Hospital medical school as chemical pathologist. Dr. Maclagan took his M.D. in 1935 and his D.SC. last year. He is also a fellow of the Royal Institute of Chemistry. His most recent work includes papers on liver function.

University of Dublin

On Dec. 3 at the school of physic, Trinity College, the following degrees were conferred:

M.A.O.—J. A. O'N. Mulcahy.

M.B., B.Ch., B.A.O.—Kurt Adler, C. L. S. Archer, Irene R. Christie, R. F. E. Coolican, Kathleen P. E. Crawford, Samuel Davis, J. R. Evans, Katherine S. P. Hill, Margaret W. Lamb, D. E. Mellon, T. J. Mills, P. R. Oliver, Irene S. Orgel, J. R. F. Smith, F. E. Williams, R. J. Yorke.

Royal College of Physicians of London

Dr. C. M. Fletcher will deliver the Goulstonian lectures at the college on Tuesday and Thursday, Jan. 13 and 15, at 5 P.M. He is to speak on Pneumoconiosis of Coalminers.

Royal College of Obstetricians and Gynæcologists

At a meeting of the council held on Nov. 22, with Mr. William Gilliatt, the president, in the chair, the honorary fellowship was conferred on Field-Marshal Jan Smuts.

The following were admitted to the membership of the college:

R. J. McC. Jamieson, Joan E. W. Mackie, Stephen Parlee (absentia), Ada Sau Haan Wong (absentia).

The following candidates have satisfied the examiners for the diploma in obstetrics:

K. D. G. Abbott, E. A. J. Alment, G. J. Amiel, Geoffrey Anderton, J. K. Armstrong, W. C. Astley, Winifred N. Backhouse, A. B. Backus, Henrietta E. Banting, C. P. Bennett, W. R. Bodenham, C. C. Bowley, Michael Bruser, C. J. Champ, J. S. L'A. Chesshire, S. N. Cole, John Colquhoun, Janet E. W. Copland, J. M. G. Costello, H. H. Crabb, Robert Crawford, R. C. Cummin, D. V. Cummins, Nora C. Curran, Reginald Cutts, C. H. De Boer, N. S. Devi, C. J. Dewhurst, L. W. D. Drabble, W. J. Driscoll, Victor Drosso, J. G. Dumoulin, Alan Eckford, D. F. Edmiston, M. S. Ellensweig, John Eskell, Joseph Firth, J. H. Fisher, G. H. Flack, H. D. Freeth, H. J. Friend, R. W. Grayburn, E. G. Hall, Archibald Hanton, S. L. Hetherington, G. E. Hewett, N. M. O'C. Hicks, Robert Hodgkinson, E. I. Holloway, D. R. Hughes, Alexander Hunter, R. W. Hutchinson, C. G. Irwin, S. B. Jahan, E. W. Jeyaratnam, Arthur Joffe, F. W. Johnson, E. P. Jones, E. W. Jones, R. A. S. Keighley, P. G. S. Kennedy, R. W. Kennon, P. M. Kerr, J. E. Kerton, B. T. Kieft, Muriel G. King, Gouri Kirtane, W. H. Laird, J. L. Lawrence, R. P. Lawrie, J. B. Lawson, J. McL. Lees, M. H. Lloyd, Mary Love, Hugh McColl, Kathleen A. McDonald, Richmond McIntosh, Muriel MacKenzie, A. G. MacLeod, J. C. MacWilliams, A. S. Majury, H. N. Mansfield, Annamma Mathan, T. K. Maurice, T. D. F. Money, Ivy M. Morgans, M. F. Morton, W. H. Oesterlein, G. C. Pattanayak, J. H. Patterson, P. C. A. Posford, M. B. Quane, W. J. Ramsay, E. B. Rayner, D. H. Rea, D. D. L. Rees, J. G. Reynolds, Henry Roberts, P. S. Robinson, E. S. Rogers, Monica H. Roper, John Rushton, G. T. Rutherfoord, Helen Samson, Mary A. Saunders, P. G. Seed, Elizabeth S. M. Sherrard, D. W. Shields, Irene M. S. Sloper, Leonard Smalley, A. A. Smith, E. M. Southern, Elizabeth M. Stokes, Alan Taylor, A. P. Walker, John Watson, Joyce Watson, A. E. B. de C. Wheeler, Joel Wilbush, Mary L. Williams, R. B. Wilson, C. H. F. Wood, Esme M. Wren, R. B. Wright.

Industrial Injuries Advisory Council

Sir Wilfrid Garrett, late chief inspector of factories, has been appointed chairman of this council, which has been set up to advise the Minister of National Insurance on questions relating to the National Insurance (Industrial Injuries) Act, 1946. The 15 other members include Prof. R. E. Lane, F.R.C.P., and Mr. E. A. Nicoll, F.R.C.S.E.

and seven years afterwards full physician. In 1908 the Graham research fund was instituted and Bolton was selected as its first director. The duties of this appointment were at first limited to the supervision and encouragement of research in the medical school, but within a few years they were enlarged to cover in addition the undergraduate teaching of general pathology. In 1914, when the directorship was joined to a full-time chair in pathology, he was succeeded by the late A. E. Boycott.

During the 1914–18 war Bolton was in charge of the medical patients of the war block at U.C.H., and for these services he was appointed O.B.E. in 1920. The Royal College of Physicians had elected him to their fellowship in 1909, and from 1933 to 1936 he was censor. He was elected F.R.S. in 1918. After being senior physician to his hospital for several years he retired from his appointments in 1935.

Few British physicians in the present century have been so successful as Bolton in combining the practice of medicine with research. Throughout his professional life he believed that a teacher in a large London medical school should actively investigate some problem in disease, and he had little sympathy with the present tendency to separate research from teaching appointments. In the course of his career he had three main research interests, and from these he seldom strayed. His early experience as a medical officer in a fever hospital deeply interested him in diphtheria, and a number of his early papers were devoted to its nervous and circulatory sequelæ. Later he turned to the investigation of cardiac œdema and gastric ulcers. For over thirty years he continued to work at these two problems, and few years went by without some published contribution upon one or both. Much of his work on œdema he brought together in his Oliver-Sharpey lectures in 1917, and on peptic ulcers in his classical monograph on *Ulcers of the Stomach* in 1913 and in his Croonian lectures on the Interpretation of Gastric Symptoms in 1928. In his research he was greatly influenced by the functional and experimental pathology of Cohnheim. He made most careful studies upon his patients to determine as closely as possible the morphological and physiological disturbances from which they suffered. He then attempted to reproduce the condition in animals in order to give greater scope for further experimental studies, and in such work his ingenuity and technical skill were outstanding. Although his main concern was always to discover the underlying functional disturbances, he spent much time on the problems of treatment, and a large proportion of his published papers were devoted to this practical aspect of medicine.

Most of Bolton's earlier papers were entirely the products of his own hands and pen, but after the 1914–18 war he collaborated more frequently. In 1922 he published with G. W. Goodhart his first paper upon gastric physiology, and began a happy and productive association which lasted for many years. In 1928 W. G. Barnard and he published their work on passive venous congestion of the liver which had been experimentally produced in animals. Even after his retirement from hospital practice, he maintained his interest in research as actively as before. With Goodhart he continued his study of duodenal regurgitation as a factor in the regulation of gastric acidity, while embarking with Payling Wright on the investigation of the paths of absorption of amino-acids from the intestines. Only on the outbreak of war in 1939, when research in the London medical schools had become almost impossible, did he reluctantly give up what had been a lifelong interest.

No-one who worked with Bolton failed to come under the spell of his personality. A fair Yorkshireman, of traditional build and appearance, he was an imposing figure in any group. While he was transparently forthright in his dealings and commanded the respect of his colleagues and assistants, his geniality shone through all his associations with his friends and patients, and no member of the staff at U.C.H. in his time was regarded more affectionately by his juniors and students. Recently one of his colleagues, F. M. R. Walshe, has again drawn attention to the objects of a teaching hospital—"to advance knowledge, to train doctors and to set an example of practice." By his success in all these objects Bolton was an outstanding figure in a particularly flourishing period in the history of his hospital.

In 1911 Charles Bolton married Ethel, the daughter of the late Henry George, who survives him.

THE LATE SIR JOHN FRASER

Prof. J. R. Learmonth writes: "Will you allow me to pay my personal tribute to Sir John Fraser? I have known and respected the man and his work for many years, when my appointment eight years ago to the systematic chair brought me into closer relationship with him. No-one could have been kinder to the newcomer. Naturally, I turned to him for guidance, and had from him wise counsel, proffered in that almost diffident way which must be familiar to the many who sought his advice, and which was inherent in the modest shy spirit that was his. Early in his life he must have forced himself to overcome his reserve, when occasion demanded, for it was clear to me that he had become a part of Edinburgh, and of Scotland, active in every cause in which he could help; and so acquiring a knowledge of people and of affairs which made him the ideal mediator (arbitrator would be the more accurate term but he would have scorned it) who unfailingly achieved the possible, as only the selfless can. For this subjection he placated his reserve by generosities and kindnesses especially to children, of number and extent known to none but himself.

"To my mind his professional work, prodigious in volume as it was, embracing all classes of society (though I doubt if he recognised these), and drawn from as wide an orbit as any I have known, provided a complete answer to the view held in some quarters that a great mind cannot obtain intellectual satisfaction from the practice of surgery. When he came to my wards in consultation he would arrive—with that attractive slightly rolling gait—radiating hope and confidence: listen attentively to the history; make the deft and gentle examination that only he could; and then stand back a little, in the attitude so many will remember—head a little to the right, the right eye half-closed, the quizzical smile. Then came the opinion—obscurities clarified, a diagnosis, a line of treatment strained to the limit to secure any hope of favourable outcome. A word or two of encouragement to the patient, and he was gone. The experience was always fresh and always instructive.

"In his operating-theatre he was the artist. Confidence there was, sureness of touch, impeccable technique: and something more. Whatever he was doing, he gave one the impression of being in the throes of creation; each procedure was to him the making of a masterpiece. I remember so well, as I watched his last operating session in the Royal Infirmary—when he had, quite characteristically, set himself only one or two minor tasks—searching in my mind for the right word to describe his use of the gauze swab. 'Swabbing' and 'mopping' could be easily discarded; 'patting' expressed the correct amount of physical effort, but was too trite: 'caressing' seemed to me to be the word. The artist was at work, absorbed in his creation.

"To give up surgery for the principalship of the university must have been a trying decision for him, and to some it seemed that the transition would be too abrupt, that the previous life of service was unsuited to the direction of great academic and business affairs. Any doubts were speedily set at rest. He was an admirable expositor, both on formal occasions and in committee; and he acquired the ability to refuse—albeit courteously—an ability of which he had not shown evidence during his professional life. His plans for the university were on a lofty scale yet evolved with a precision of detail which had been the habit of his life. Some have come to fruition, some are in the making; his love for his university permeated all.

"Last Thursday afternoon every street in Edinburgh seemed to lead to St. Giles. The ceremony was an intensely moving one: the colourful pomp of the congregation, the service almost severe in its simplicity. But the tribute which would have pleased him most was the great gathering of those who, unable to gain admittance to the crowded cathedral, waited bareheaded outside the west door in the grey December dusk. His old patients come to take their leave of him."

ATMENT OF TUBERCULOSIS WITH STREPTOMYCIN AND SULPHETRONE

D. G. MADIGAN
M.B. N.U.I.

P. N. SWIFT

With an addendum on
The Histology of Typical Lesions after Streptomycin

G. PAYLING WRIGHT
D.M. Oxfd, F.R.C.P.
SIR WILLIAM DUNN PROFESSOR OF PATHOLOGY,
GUY'S HOSPITAL MEDICAL SCHOOL

STREPTOMYCIN can favourably modify the course of perimental inoculation tuberculosis in animals, even ugh it cannot be relied on to eliminate the causal anism (Smith and McClosky 1945, Feldman et al. 5, Brownlee and Kennedy 1948b). When the infecting is sufficiently large, the disease, though partly pressed, progresses throughout the period of observa- (Brownlee and Kennedy 1948b) and there is no dence of bactericidal activity in vivo. The same kers show that the susceptibility of the organisms ains unchanged after streptomycin and 'Sulphetrone' atment in guineapigs.

From the published reports it is apparent that the tibiotic can influence clinical tuberculosis to a limited tent and under certain conditions. Thus Baggenstoss al. (1947) report a fatal termination to 5 cases of liary tuberculosis in children even though the disease the lungs was favourably modified. The dosage in e cases seemed adequate, yet streptomycin could be demonstrated in brain substance in which tuberous lesions were observed. An earlier report by shaw et al. (1946) records the survival of 4 out of patients with proved tuberculous meningitis and provement after treatment of surface lesions of the rynx, trachea, and large bronchi. Once again all out of 3) patients with miliary tuberculosis died. In r types of tuberculosis (peritoneal, skeletal, hepatic, tract, empyema, and cutaneous fistulæ) no per- ment improvement could be demonstrated. It is eresting, in view of the observations reported here, t improvement with sputum reversal was recorded 19 out of 24 cases of pulmonary tuberculosis.

Among the most impressive experimental evidence of the chemotherapeutic activity of antituberculotic drugs are the histological signs of healing of established tubercles in animals and man. Confirmatory evidence of this kind is presented here for man and is entially similar to the histological evidence of healed miliary tubercles reported by Baggenstoss et al. (1947).

Like other drugs of natural origin, streptomycin has presented problems of purification. Besides having an intrinsic toxicity, commercially prepared streptomycin is more or less contaminated with impurities, important among which are pressor bases, depressor bases, and substances which damage the renal epithelium. The material used by us in the present trial was free from these impurities (Madigan et al. 1947) and appeared to owe such toxicity as it did possess to streptomycin itself. Further complications, however, should be clearly recognised. The possibility discussed by Madigan et al. (1947) that more than one streptomycin exists has been confirmed in the record of a third different molecule by us and Fried (1947).

METHODS AND CLINICAL MATERIAL

The opportunity to compare the efficacy of streptomycin with that of sulphone chemotherapy arose in June, 1946, with the supply of a limited quantity from the Wellcome Foundation in the form of seventeen batches which had been pharmacologically controlled. The material was supplied as a freeze-dried powder in phials containing the equivalent of 0·2 g. of pure streptomycin base, together with a supply of sterile pyrogen-free distilled water. Extensive biological control, reported in detail elsewhere (Madigan et al. 1947), had been exercised. The material had been tested for sterility and for freedom from pyrogens, histamine-like impurities, and, with one exception, antidiuretic substances. The average lethal dose of these batches in an acute experiment in mice was less than that of pure streptomycin. Towards the end of the trial it was necessary to use (intramuscularly) one batch of streptomycin which did not conform to these standards. Its history made it obvious that the histamine-like substances and pressor bases which it contained, in small amount, originated from a bacterial contaminant of the culture medium. For the purpose of intrathecal injection it was found that an isotonic solution resulted when the contents of one phial (0·2 g.) were dissolved in 18 ml. of distilled water. In practice 0·2 g. of streptomycin was dissolved in 2 ml. of distilled water, but even with such a hypertonic solution no acute toxic effects were seen.

Sulphetrone, which was included in the trial, is 4 : 4′-bis(γ-phenyl-N-propylamino)diphenylsulphone-tetrasodium sulphonate, the pharmacology and chemotherapy of which will shortly be described (Brownlee et al. 1948). Shown to modify favourably the course of inoculation tuberculosis of virulent human and bovine origin in guineapigs (Brownlee and Kennedy 1948a), it appears to be a slightly more efficient antituberculotic sulphone-derivative than 'Diasone' or 'Promin' and compares favourably with promin in the treatment of experimental tuberculosis in the guineapig (Brownlee and Kennedy 1948b). Its claim to superiority as the sulphone of choice rests on its lack of acute and chronic toxicity, in that adequate blood-sulphetrone levels have been maintained in man for longer than 12 months. (The full clinical reports of Anderson and Strachan (1948), Clay and Clay (1948), and Madigan (1948) are in preparation.)

The established regimen aims at obtaining and maintaining a blood-sulphetrone level of 7·5–10·0 mg. per 100 ml. of blood in patients treated in hospital. The daily dose is 6–9 g., fluids being restricted to 3 pints. During the period of adjustment, spread over some ten days, the initial daily dose of 1·5 g. is gradually increased. Fresh yeast and iron are given by mouth before and during treatment.

Two studies were made—(1) to assess the efficacy of streptomycin; and (2) to evaluate the possible synergic action of streptomycin and sulphetrone, in the light of the significant synergic action between streptomycin and sulphetrone reported in tuberculous guineapigs by Brownlee and Kennedy (1948b).

The limited supply of streptomycin restricted the experiment to 17 cases. The choice of clinical material was dictated by its presence in the hospital; but the main manifestations of human tuberculosis were covered.

CASE-RECORDS

Group I (Streptomycin only)

Case 1.—Girl, aged $2^1/_2$ years, admitted to hospital July 20, 1946, with *tuberculous meningitis*, intermediate stage, bacteriologically proved.

Treatment.—Streptomycin 0·2 g. intramuscularly four-hourly plus 0·2 g. intrathecally once daily from July 29 to Aug. 10 (13 days). After 24 hours' treatment, level in cerebrospinal fluid (C.S.F.) 6·4 µg. per ml.; blood level 16 µg. per ml.

Course.—Modified favourably, but patient died on Aug. 10.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on Dec. 1, with Prof. G. B. Fleming, the president, in the chair, the following were admitted to the fellowship:

Graham Herbert Anderson, Edward Kenyon Blackburn, Samuel Dunn, Rankine Good, Arthur Thomson Hendry, James Hood, William Macfarlane Lancaster, Thomas Davidson Veitch Lawrie, George McCracken, Alastair Goold Macgregor, Robert Montgomery, Archibald Walker Sloan, George Will, qua physicians; John Cuthbertson Jeffrey, Alexander Macpherson Keith, Shreedhar Shreenivas Kirtane, Andrew Bruce MacLean, Norman McSwan, William Albert Watt Maney, Purushottam Bhagwant Sulakhe, Andrew Tomney, William Arthur Leigh Tucker, Stuart Young, qua surgeons.

Royal College of Surgeons in Ireland

The following have been successful in the fellowship examination: D. P. Beckett, R. E. Fenelon, R. S. Murray, J. R. McElroy.

Human-milk Bank at Cardiff

A human-milk bank has been opened at City Lodge Hospital, Cardiff. There is a similar bank at Queen Charlotte's Hospital, London; and plans for the establishment of a bank in Birmingham were announced last May (*Lancet*, 1947, i, 774).

Naval Appointment

Surgeon Captain L. F. Strugnell has been promoted surgeon rear-admiral and appointed deputy medical director-general of the Navy in succession to Surgeon Rear-Admiral A. E. Malone.

Delinquency and the Educator

A course of six lectures on this subject will be given at the Institute for the Scientific Treatment of Delinquency, 8, Bourdon Street, London, W.1, by Miss Barbara Low, B.A., on Jan. 27, Feb. 3, 13, 24, March 2 and 9, at 6.30 P.M.

Volunteers Needed by Common Cold Unit

Further volunteers are required by the Common Cold Research Unit, Salisbury, for intranasal inoculation with fluid which sometimes contains the cold virus. Sessions which are not filled are the 10-day periods beginning Jan. 14 and 28, Feb. 11 and 25, March 10, April 14 and 28, May 26, and June 9. Further information is obtainable from the medical officer, Harvard Hospital, Coombe Road, Salisbury.

Red Cross Relief in India

Major-General T. O. Thompson, C.B., M.D., has been released by the Army to serve as British Red Cross commissioner in India and Pakistan. In view of the likelihood of exceptionally serious epidemics next spring, especially among refugees, the society has authorised the formation of mobile hospitals, ambulance convoys, and teams of specialists, and it has already dispatched supplies of penicillin, vitamins, and blood-plasma.

Epsom College

The council invites applications for a France pension of £30 per annum for a necessitous medical man fully 55 years of age, who has been registered for 5 years.

There are also available other pensions and grants for medical practitioners or widows, when vacancies occur, and scholarships and grants for boys and girls (not necessarily orphans) of public-school age and in need of such help.

Forms of application may be obtained from the secretary's office, Epsom College, Surrey.

Appointments

The Hospital for Sick Children, Great Ormond Street, London:

FAGG, C. G., M.B. Lond., D.C.H.: house-physician.
KING, ALISON, M.B. Edin.: house-surgeon.
REDSHAW, JOAN, M.B. Sydney, D.C.H.: house-surgeon.
WILSON, B. D., M.B. Lond., M.R.C.P., D.C.H.: house-physician.

London County Council Mental Health Service:

BATT, J. C., M.D. Brist., M.R.C.P., D.P.M.: physician deputy superintendent, St. Ebba's Hospital, Epsom.
SHAW, DAVID, M.D. Lond., M.R.C.P., D.P.M.: physician deputy superintendent, Sutton Emergency Hospital, Surrey.

Ministry of Pensions Medical Services Division:

CURRAN, KEVIN, M.B. N.U.I.: surgical officer B2, Rookwood Hospital, Cardiff.
DUNCAN, MARGARET, M.B. St. And.: medical officer B2, Rookwood Hospital, Cardiff.
JAMES, T. G. S., M.A., M.B. Camb.: medical officer B2, Queen Mary's Hospital, Roehampton.
THOMSON, G. R., M.B. Glasg.: surgical officer B1, Stoke Mandeville Hospital, Aylesbury.

Diary of the Week

DEC. 14 TO 20

Monday, 15th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Mr. D. W. C. Northfield: Intracranial Hy dynamics.
5 P.M. Prof. Alexander Haddow: Carcinogenesis.
HUNTERIAN SOCIETY
8.30 P.M. (Talbot Restaurant, London Wall, E.C.2.) Aleck Bourne, Dr. Edward Sharp, Mr. John How Menstrual Disorders in Relation to General Medicine.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Port Place, W.1
3 P.M. Prof. E. D. Adrian, O.M., F.R.S.: Elements of Ner Activity. (First Harben lecture.)

Tuesday, 16th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. C. M. West: The Skin.
5 P.M. Prof. S. L. Baker: Absorption and Deposition of F
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. J. E. M. Wigley: Pemphigus Group of Eruptions
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE
3 P.M. Professor Adrian: Effects of the Sense Organs. (Se Harben lecture.)
EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Dr. J. A. F. Roberts, Dr. Eliot Slater: Genetics, Medicine, Practical Eugenics.

Wednesday, 17th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. John Beattie: Autonomic Nervous Sy (Central).
5 P.M. Prof. J. W. S. Blacklock: Surgical Tuberculos Bovine Origin.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE
3 P.M. Professor Adrian: Activity of the Brain. (Last Ha lecture.)

Thursday, 18th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. E. G. T. Liddell, F.R.S.: Pyramidal Ner System.
5 P.M. Dr. J. Hamilton-Paterson: Reticulosis and Ly gland Enlargement.

Friday, 19th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. J. Douglas Robertson: Calcium Metabolism.
5 P.M. Dr. Hamilton Paterson: Myelomata and Their Relatio the Hæmopoietic Bone-marrow.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8 P.M. *Obstetrics and Gynæcology.* Mr. Everard Williams, Catherine Lewis, Mr. Ogier Ward: Urological Prob in Relation to Gynæcological Surgery, with Sp Reference to the Vesico-vaginal Fistula and the Div Ureter.
LONDON CHEST HOSPITAL, Victoria Park, E.2
5 P.M. Dr. Franklin Wood: X-ray Kymography of the H and Lungs.

Births, Marriages, and Deaths

BIRTHS

GILLETT.—On Dec. 6, at Altrincham, Cheshire, the wife of Dr. R Gillett—a son.
SPENCER.—On Dec. 1, at Newcastle, the wife of Dr. Seym Spencer—a son.
STANBRIDGE.—On Dec. 2, at No. 8 R.A.F. Hospital, Germa the wife of Group-Captain R. H. Stanbridge, O.B.E.—a son.
STOTT.—On Dec. 4, at Chobham, the wife of Dr. Norman Stot a son.
TAYLOR.—On Nov. 28, at Aberdeen, the wife of Dr. J. L. Taylo a daughter.
TODD.—On Nov. 28, at Leicester, the wife of Dr. R. M. Tod a son.
WALKER.—On Nov. 29, in London, the wife of Dr. David Walker a daughter.
WELFORD.—On Nov. 25, the wife of Dr. N. T. Welford—a daught

MARRIAGES

BENNETT—CRANE.—On Nov. 28, in London, Reginald Bennet B.M., to Henrietta Margaret Crane.
IRVING—BAILLIE.—On Nov. 29, at Bletchingley, Sir Miles Irvi C.I.E., O.B.E., to Emily Elspeth Grace Baillie, M.B.
McCAULEY—TUCHMANN.—On Nov. 20, in London, Francis Jos McCauley, B.ARCH., to Anna Marie Tuchmann, M.B.

DEATHS

BOLTON.—On Dec. 6, in London, Charles Bolton, C.B.E., D.S M.D. Lond., F.R.C.P., F.R.S.
FLEMING.—On Dec. 5, at Kinloch Rannoch, Robert Alexand Fleming, M.A., LL.D., M.D. Edin., F.R.C.P.E., F.R.S.E., aged 85.
FRASER.—On Dec. 1, in Edinburgh, Sir John Fraser of Tain, baron M.D. Edin., LL.D., F.R.C.S.E., F.A.C.S., F.R.A.C.S., F.R.C.P.E., F.R.S
HIGGIN.—On Nov. 29, at Newton Abbot, Robert Francis Higg B.A., M.D. Camb.
LACEY.—On Nov. 29, in Cape Town, Bernard Warner Lac M.B. Durh.
SCOTT.—On Nov. 20, at Exeter, Robert Scott, M.B. Glasg.
THOMSON.—On Dec. 2, in London, William Brown Thom M.D. Glasg., D.P.H., aged 68.
URSELL.—On Dec. 4, at Cambridge, Siegfried Ursell, M.D. Munich.

ATMENT OF TUBERCULOSIS WITH STREPTOMYCIN AND SULPHETRONE

D. G. MADIGAN
M.B. N.U.I.

P. N. SWIFT
M.R.C.S.

GEORGE BROWNLEE
B.Sc. Glasg., Ph.D. Lond.

the Tuberculosis Chemotherapy Unit, County Hospital, Farnborough, Kent, and the Wellcome Physiological Research Laboratories, Beckenham

With an addendum on the Histology of Typical Lesions after Streptomycin

G. PAYLING WRIGHT
D.M. Oxfd, F.R.C.P.
SIR WILLIAM DUNN PROFESSOR OF PATHOLOGY, GUY'S HOSPITAL MEDICAL SCHOOL

REPTOMYCIN can favourably modify the course of rimental inoculation tuberculosis in animals, even h it cannot be relied on to eliminate the causal nism (Smith and McClosky 1945, Feldman et al. 6, Brownlee and Kennedy 1948b). When the infecting e is sufficiently large, the disease, though partly ressed, progresses throughout the period of observa- n (Brownlee and Kennedy 1948b) and there is no ence of bactericidal activity in vivo. The same ters show that the susceptibility of the organisms ains unchanged after streptomycin and 'Sulphetrone' ment in guineapigs.

From the published reports it is apparent that the biotic can influence clinical tuberculosis to a limited ent and under certain conditions. Thus Baggenstoss al. (1947) report a fatal termination to 5 cases of ary tuberculosis in children even though the disease the lungs was favourably modified. The dosage in e cases seemed adequate, yet streptomycin could be demonstrated in brain substance in which tuber- us lesions were observed. An earlier report by haw et al. (1946) records the survival of 4 out of patients with proved tuberculous meningitis and rovement after treatment of surface lesions of the ynx, trachea, and large bronchi. Once again all ut of 3) patients with miliary tuberculosis died. In er types of tuberculosis (peritoneal, skeletal, hepatic, l tract, empyema, and cutaneous fistulæ) no per- ent improvement could be demonstrated. It is resting, in view of the observations reported here, e improvement with sputum reversal was recorded 12 out of 24 cases of pulmonary tuberculosis.

mong the most impressive experimental evidence of e chemotherapeutic activity of antituberculotic drugs the histological signs of healing of established ercles in animals and man. Confirmatory evidence this kind is presented here for man and is ntially similar to the histological evidence of ed miliary tubercles reported by Baggenstoss et al. (1947).

Like other drugs of natural origin, streptomycin has ented problems of purification. Besides having an insic toxicity, commercially prepared streptomycin is re or less contaminated with impurities, important ng which are pressor bases, depressor bases, and stances which damage the renal epithelium. The material used by us in the present trial was free from these urities (Madigan et al. 1947) and appeared to owe h toxicity as it did possess to streptomycin itself. rther complications, however, should be clearly ognised. The possibility discussed by Madigan et al. (1947) that more than one streptomycin exists has been firmed in the record of a third different molecule by ns and Fried (1947).

METHODS AND CLINICAL MATERIAL

The opportunity to compare the efficacy of streptomycin with that of sulphone chemotherapy arose in June, 1946, with the supply of a limited quantity from the Wellcome Foundation in the form of seventeen batches which had been pharmacologically controlled. The material was supplied as a freeze-dried powder in phials containing the equivalent of 0·2 g. of pure streptomycin base, together with a supply of sterile pyrogen-free distilled water. Extensive biological control, reported in detail elsewhere (Madigan et al. 1947), had been exercised. The material had been tested for sterility and for freedom from pyrogens, histamine-like impurities, and, with one exception, antidiuretic substances. The average lethal dose of these batches in an acute experiment in mice was less than that of pure streptomycin. Towards the end of the trial it was necessary to use (intramuscularly) one batch of streptomycin which did not conform to these standards. Its history made it obvious that the histamine-like substances and pressor bases which it contained, in small amount, originated from a bacterial contaminant of the culture medium. For the purpose of intrathecal injection it was found that an isotonic solution resulted when the contents of one phial (0·2 g.) were dissolved in 18 ml. of distilled water. In practice 0·2 g. of streptomycin was dissolved in 2 ml. of distilled water, but even with such a hypertonic solution no acute toxic effects were seen.

Sulphetrone, which was included in the trial, is 4 : 4′-bis-(γ-phenyl-N-propylamino)diphenylsulphone-tetrasodium sulphonate, the pharmacology and chemotherapy of which will shortly be described (Brownle et al. 1948). Shown to modify favourably the course o inoculation tuberculosis of virulent human and bovin origin in guineapigs (Brownlee and Kennedy 1948a), i appears to be a slightly more efficient antituberculoti sulphone-derivative than 'Diasone' or 'Promin' and com pares favourably with promin in the treatment of experi mental tuberculosis in the guineapig (Brownlee an Kennedy 1948b). Its claim to superiority as the sulphon of choice rests on its lack of acute and chronic toxicity in that adequate blood-sulphetrone levels have bee maintained in man for longer than 12 months. (The fu clinical reports of Anderson and Strachan (1948), Cla and Clay (1948), and Madigan (1948) are in preparation.

The established regimen aims at obtaining and main taining a blood-sulphetrone level of 7·5–10·0 mg. pe 100 ml. of blood in patients treated in hospital. Th daily dose is 6–9 g., fluids being restricted to 3 pint During the period of adjustment, spread over some te days, the initial daily dose of 1·5 g. is gradually increase Fresh yeast and iron are given by mouth before an during treatment.

Two studies were made—(1) to assess the efficacy o streptomycin; and (2) to evaluate the possible synergi action of streptomycin and sulphetrone, in the light o the significant synergic action between streptomycin an sulphetrone reported in tuberculous guineapigs b Brownlee and Kennedy (1948b).

The limited supply of streptomycin restricted th experiment to 17 cases. The choice of clinical materia was dictated by its presence in the hospital: but th main manifestations of human tuberculosis were covered

CASE-RECORDS

Group I (Streptomycin only)

Case 1.—Girl, aged $2^1/_2$ years, admitted to hospital July 2 1946, with *tuberculous meningitis*, intermediate stage, bacteri logically proved.

Treatment.—Streptomycin 0·2 g. intramuscularly fou hourly plus 0·2 g. intrathecally once daily from July 29 t Aug. 10 (13 days). After 24 hours' treatment, level in cerebr spinal fluid (C.S.F.) 6·4 µg. per ml.; blood level 16 µg. per m

Course.—Modified favourably, but patient died on Aug. 3

Case 2.—Man, aged 34, admitted *Nov. 19, 1946*, with *tuberculous meningitis*, late stage, bacteriologically proved.

Treatment.—Streptomycin 0·2 g. intramuscularly four-hourly plus 0·2 g. intrathecally once daily from Nov. 19 to Nov. 21 (3 days). At 24 hours, blood level 8 μg. per ml.; C.S.F. level 6·0 μg. per ml.

Course.—No modification; patient died on Nov. 22.

Case 3.—Boy, aged 16, admitted Sept. 24, 1946, with *tuberculous meningitis*, late stage, bacteriologically proved.

Treatment.—Streptomycin 0·2 g. intramuscularly four-hourly plus 0·2 g. intrathecally once daily from Sept. 26 to Oct. 3 (8 days). At 24 hours, blood level 16 μg. per ml.; C.S.F. level 6·4 μg. per ml.

Course.—No modification; patient died on Oct. 3.

Case 4.—Boy, aged $1^1/_2$ years, admitted Nov. 4, 1946, with *tuberculous meningitis*, late stage, bacteriologically proved.

Treatment.—Streptomycin 0·2 g. intramuscularly four-hourly plus one dose of 0·2 g. intrathecally from Nov. 4 to Nov. 5 (1 day). At 24 hours, blood level 8 μg. per ml.; C.S.F. level 3·2 μg. per ml.

Course.—No modification; patient died on Nov. 5.

Case 5.—Man, aged 26, admitted Nov. 26, 1946, with *tuberculous meningitis* proved subsequently by guineapig inoculation and associated with extensive bilateral fibro-caseous pulmonary tuberculosis. *Myc. tuberculosis* grown from sputa. Radiography showed infiltration of upper half of left lung, with cavitation; tuberculous infiltration of right upper zone.

Treatment.—Streptomycin from Nov. 27, 1946, to Feb. 17, 1947 (83 days). The initial daily dosage was 1·2 g., of which 0·2 g. was given intrathecally. At 24 hours, blood level 8·2 μg. per ml.; C.S.F. level 24 μg. per ml. From Nov. 28, 1946, to Feb. 17, 1947, the dosage was 2·4 g. daily, of which, from Dec. 14 to Jan. 27, 0·4 g. daily was given intrathecally. After 24 hours on this higher dosage, blood level was 16·4 μg. per ml; C.S.F. level 82 μg. per ml. Heparin 2 mg. was given intrathecally daily from Jan. 2 to Jan. 27.

Course.—During the exhibition of streptomycin there was some remission of the clinical manifestations of meningitis. After the withdrawal of intrathecal streptomycin on Jan. 28 (62nd day) there was continuous improvement until March 4 (98th day), when no evidence of clinical meningitis was detected. There was a lag in the return of the C.S.F. to normal. No demonstrable change in lungs.

Case 6.—Woman, aged 29, admitted moribund Sept. 21, 1946, with *acute caseous tuberculous pneumonia*, bacteriologically proved, involving extensive area of right lung. Polypnœa required continuous oxygen. Radiography showed consolidation of right upper lobe and part of right lower lobe. Serial radiography showed extension of process in right lung with spread to left lung.

Treatment.—Streptomycin 0·2 g. intramuscularly four-hourly daily from Oct. 17, 1946, to Jan. 14, 1947 (89 days). Blood level 6·4 μg. per ml.

Course.—Clinical improvement. Serial radiograms showed less consolidation in right lung and apparent opening up of air spaces, but honeycombing of right upper lobe. Patient died on Jan. 14.

Case 7.—Boy, aged 16, admitted July 8, 1946, with *acute caseous tuberculous pneumonia* of left upper lobe, bacteriologically proved, with extensive bronchogenic spread. Severe constitutional disturbance. Radiography showed three segments of left upper lobe atelectatic, with large dorsal cavity; mottling of left lower zone; heart and trachea displaced to left; ground-glass shading of right upper lobe. Serial radiograms showed right paramediastinal area mottled; heavy mottling of right cardiophrenic and costophrenic angles. Extensive infiltration of left upper and lower lobes.

Treatment.—Intramuscular streptomycin 0·2 g. four-hourly from July 16 to Oct. 16, 1946 (92 days). Blood level 6·0 μg. per ml.

Course.—General condition improved. Hectic temperature reduced after 12 days of streptomycin course, but between July 8 and 27 there was a serious bronchogenic spread in right lower lobe, clinically and radiologically. Radiography on 67th day revealed remarkable clearing of right lung and reduction of infiltration in left lower lobe. Sputum not reversed. Erythrocyte-sedimentation rate (E.S.R.) unaltered.

Review at 6 months: active intervention necessary to control disease. Condition deteriorating.

Case 8.—*Girl, aged 19,* admitted Jan. 18, 1946, wi bacteriologically proved *hæmatogenous tuberculosis* originati in mediastinal glands and involving lungs, 3rd lumbar verteb and right sacro-iliac joint. Severe constitutional disturbanc Proved tuberculous abscess over upper end of right sacr iliac joint. Radiography showed loss of joint space betwe T8 and T9; erosion of lower and outer part L3; slight bo changes in right sacro-iliac joint; widespread hæmatogeno patchy infiltration of both lungs.

Treatment.—Intramuscular streptomycin 0·2 g. four-hour from July 23 to Oct. 15, 1946 (84 days). Blood level 9·0 μ per ml.

Course.—General improvement excellent. E.S.R. (Cutl fell from 20–30 mm. to 7–10 mm. (normal 2–10 mm.). Weig increased 2 st. Radiography: original foci in lungs harden and shrunk; spine unchanged.

Review at 6 months: progressive improvement; no tube bacilli found in sputum since Jan. 29, 1946.

Case 9.—Woman, aged 27, admitted May 22, 1946, wi *bacteriologically proved tuberculous bronchopneumonia* a right pleural effusion. Pronounced constitutional disturban Radiography showed bronchopneumonic mottling of rig apical and mid zones; right pleural effusion; slight mottli of left lower lobe. Second series of radiograms a month lat showed more pronounced mottling in both lungs.

Treatment.—Intramuscular streptomycin 0·2 g. four-hour from July 11 to Oct. 3, 1946 (84 days). Blood level 6·4 μ per ml.

Course.—Temperature dropped from 98–99 8° to 97·6–97 during course, and to normal 16 days before end of cour Weight increased 8 lb. E.S.R. (Cutler) fell from 25 mm. 18 or 10 mm. Sputum, which at first contained tube *bacilli*, contained none on Aug. 8, after which there w no sputum up to Jan. 2, 1947. Radiography showed th original soft focal mottling became harder and less den and pleural effusion was absorbed.

Review at 6 months: condition static; tubercle ba again appeared in sputum: radiography showed appare further clearing of mottling, but there was a small cavi at level of right 1st interspace and a large one of tens type in apex of right lower lobe.

Case 10.—Girl, aged 7 years, admitted Sept. 18, 194 with *acute miliary tuberculosis and terminal tuberculous men gitis*, bacteriologically proved. Constitutional disturban limited to high temperature. Radiography on Sept. 1 showed classical picture of fine miliary tubercles.

Treatment.—Intramuscular streptomycin 0·2 g. four-hour from Sept. 18 to Dec. 18, 1946 (89 days). From Nov. to Dec. 12 0·2 g. was given intrathecally once daily. 24 hours, C.S.F. level 6·4 μg. per ml.; blood level 16 μg. per m

Course.—Much clinical improvement until 65th da when onset of clinical meningitis was noted. Serial radi grams showed progressive clearing of miliary lung pictur Radiogram on 88th day appeared completely normal. O 71st day clinical meningitis was manifest, which pursue its usual course until death on 89th day (Dec. 18).

Case 11.—Man, aged 25, admitted Oct. 11, 1946, wit *acute generalised tuberculosis*, predominantly pulmonary an lymphatic, bacteriologically proved. Severe constitutiona disturbance. Radiography showed classical picture of fi miliary tubercles of lungs.

Treatment.—Streptomycin from Oct. 11, 1946, to Jan. 2 1947 (102 days): 1·2 g. intramuscularly daily from Oct. 11 t Nov. 13; 0·2 g. intrathecally daily from Nov. 20 to Dec. 13 At 24 hours, blood level 7·0 μg. per ml; C.S.F. level 4 8 μg per ml. Streptomycin raised to 2 4 g. intramuscularly dail from Nov. 14 to Jan. 21, with 0·4 g. intrathecally daily from Dec. 14 to Jan. 21. At 24 hours after start of higher dosage blood level 14·0 μg. per ml.; C.S.F. level 48 μg. per ml Heparin 2 mg. intrathecally given daily from Jan. 2 to 21.

Course.—Two distinct phases of almost equal duration (about 50 days). In the first phase the cervical glands regresse and the meningitis, of which clinical and cytological evidence existed on Nov. 18, disappeared by Dec. 18. Radiography showed gradual clearing of miliary picture, and by Dec. 2 lungs appeared normal except for residual miliary tubercle in left upper lobe. In the second phase the general condition deteriorated: the cervical glands enlarged and caseated and clinical evidence of mesenteric glandular involvement foreshadowed generalised lymphatic tuberculosis. Radi graphy on Jan. 13 showed generalised coarser miliary tuberc in lungs. The patient died on Jan. 21.

II (Streptomycin and Sulphetrone)

12.—Man, aged 39, admitted June 5, 1946, with *fibrocaseous pulmonary tuberculosis*, bacteriologically ved. Severe constitutional disturbance. Radiography wed acute infiltrative lesion in posterior apex; cavitation axillary area of subapical segment; infiltration in lower drant, pectoral segment of right upper lobe; infiltration pex of right lower lobe.

Treatment.—Sulphetrone from June 21, 1946, to Jan. 23, 7. Blood level 2–7 mg. per 100 ml. Intramuscular strepto- m 0·2 g. four-hourly from July 11 to Oct. 3 (84 days). od level 6·4 μg. per ml.

urse.—Hectic temperature modified 12 days after etrone; temperature became normal 3 weeks after tomycin stopped. Weight increased 11 lb. E.S.R. (Cutler) from 30 mm. to 4 mm. Tubercle bacilli were found in rous specimens of sputum up to Aug. 29, 1946. Between and Oct. 3 there were 11 negative smears, 3 negative res, and a negative animal test. Radiographic report on . 28: infiltrative process halted; cavitation now not ; acute lesion converted to chronic process.

iew at 6 months: areas of disease static, but cavity pened; sputum again positive. The patient was readmitted hospital on June 21, 1947, for collapse therapy; E.S.R. estergren) was then 28 mm. in 1st hour.

se 13.—Man, aged 47, admitted May 4, 1946, with nic *fibrocaseous pulmonary tuberculosis*, bacteriologically ved. Radiography showed fibrocaseous pulmonary lesions ight upper lobe; large cavity in right apex; fan- ped area of decreased transluceney from apex to enlarged t root; left upper lobe suspect. Serial radiograms revealed nsion of dense mottling to right middle and lower zones.

eatment.—Sulphetrone given from May 21 to Oct. 3; od level 2 mg. per 100 ml. Streptomycin 0·2 g. four-hourly en from July 11 to Oct. 3 (84 days); blood level 4·8 μg. r ml.

Course.—Diurnal temperature excursion increased, with- rsion to normal 3 days after stopping streptomycin. phases were seen. During first 2 months there were 8 tive sputa; E.S.R. (Westergren) fell from 23 mm. to mm. in 1st hour; and serial radiograms showed successive rovement. Second phase intervened at third month of apy. Radiogram on Oct. 2 showed more mottling of lower zone, with larger right apical cavity.

iew at 6 months: all sputa positive since Dec. 9; E.S.R. estergren) up to 70 mm. in 1st hour; serial radiograms rmed advance of disease. Feb. 21, 1947: onset of right ral effusion, which progressed to encysted tuberculous yema, accompanied by prostrating toxæmia, general ma, and ulceration of mouth. The patient died on Aug. 16,

Case 14.—Woman, aged 29, admitted April 27, 1945, with *bilateral tuberculous bronchopneumonia*, bacteriologically proved. Grave constitutional disturbance. Radiography showed bilateral bronchopneumonic tuberculosis affecting all lobes; and area of consolidation in right lower lobe.

Treatment.—Sulphetrone given from March 11 to Oct. 2, 1946; blood level 3 mg. per 100 ml. Streptomycin 0·2 g. four hourly given from July 11 to Oct. 3, 1946 (84 days); blood level 6·4 μg. per ml.

Course.—Slight excursion of temperature range, reduced on withdrawal of streptomycin, and normal 8 weeks later. Weight, E.S.R., and sputum unchanged. Radiography on Sept. 8, 1946, showed change to fibrocavernous lesions with evidence of calcifying foci.

Review at 6 months: extension of fibrotic changes, with foci of calcification more in evidence.

Case 15.—Boy, aged $6^1/_2$ years, admitted on Jan. 31, 1946, with *hæmatogenous pulmonary tuberculosis* of coarse miliary type, not bacteriologically proved. No meningeal symptoms; C.S.F. culture sterile. Mantoux test positive. His father had open tuberculosis. Radiography showed bilateral hæmatogenous pulmonary tuberculosis; lungs stippled with coarse miliary pattern, conforming to "chronic" miliary picture; enlarged mediastinal glands.

Treatment.—Sulphetrone given from Dec. 3, 1946, to April 17, 1947; blood level 8 mg. per 100 ml. Streptomycin given from Feb. 3 to April 17, 1947 (73 days); blood level 12·0 μg. per ml.

Course.—Clinical condition much improved. E.S.R. (Westergren) fell from 22 mm. to 18 mm. in 1st hour. Gained weight. Serial radiograms showed gradual regression of coarse miliary tubercles.

Review at 6 months: from May 30, 1947, temperature again began to swing; radiogram on June 13 showed enlargement of left root, with collapse of left subapical segment; enlarged left bronchial glands, with "hilar flare" towards subapical segment of left upper lobe; miliary mottling no longer seen; E.S.R. 52 mm. in 1st hour. Sulphetrone therapy was re-established on June 22, and by Aug. 22 E.S.R. was 6 mm. in 1st hour; weight had increased 9 lb.; radiography showed regression of root glands; and general condition had much improved.

Case 16.—Man, aged 36, admitted June 5, 1946, with *chronic renal tuberculosis*, bacteriologically proved. Ureteric catheterisation demonstrated tubercle bacilli from left kidney only. Radiography showed damage to left kidney, with some calcification.

Treatment.—Sulphetrone given from June 4 to Sept. 14, 1946; blood level 2·5 mg. per 100 ml. Streptomycin 0·2 g. four-hourly given from July 11 to Oct. 3, 1946 (84 days); blood level 10·0 μg. per ml.

Course.—No significant change.

Case 17.—Man, aged 21, admitted Sept. 13, 1945, with recently healed lesion of L2 and L3 vertebræ, *severe spinal caries* of D8–10, complicated by a large paravertebral tuberculous abscess bacteriologically proved, a large pure chylous effusion in right pleural cavity, peculiar lung mottling, enlarged cardiac shadow, and pericardial effusion. Serial radiograms to June 21, 1946, showed clearing but patchy consolidation in right lower zone, and large pear-shaped paravertebral abscess.

Treatment.—Sulphetrone given from June 21 to Dec. 19, 1946; blood level 4 mg. per 100 ml. Streptomycin 0·2 g. four-hourly given from July 11 to Oct. 3, 1946 (84 days); blood level 14·0 μg. per ml.

Course.—Positive sputum on Sept. 26, 1945, then numerous negatives (culture and animal). E.S.R. (Cutler) fell from 24 mm. to 4 mm. Weight increased 4 lb. Temperature became normal. Radiography showed lungs clearer.

Review at 6 months: clinical improvement continued; radiography showed lungs clear except for pleural thickening from right root to right cardiophrenic angle; and bony union of vertebræ T8 and T9; posterior surface of T9 wedged into T10.

CLINICAL APPRECIATION

Group I (Streptomycin only)

Cases 1–4 were of proved tuberculous meningitis in either an intermediate or a late stage. Though adequate streptomycin levels were continuously present in blood and C.S.F. for periods ranging from 8 hours to 13 days, no appreciable deviation was detected from the natural course of the disease.

Case 5 was a clinical meningitis, subsequently proved to be tuberculous by guineapig inoculation, in a patient with extensive bilateral fibrocaseous pulmonary tuberculosis. The prognosis was sufficiently grave to justify an increase of dose of streptomycin from 0·2 to 0·4 g. intrathecally for 44 days, with the result that high antibacterial levels were reached in the C.S.F. Possible obstruction of the foramina with fibrin was countered by the intrathecal injection of heparin 2 mg. (260 I.U.) daily, which immediately prevented the appearance of a fibrin web which previously had been a constant feature of withdrawn C.S.F. With the resolution of the meningitis no evidence of irreversible damage in the form of persistently raised intracranial tension, or its secondary effects, was found. The chronic pulmonary lesions, unlike those of acute miliary tuberculosis, were unaffected.

Case 6, an acute tuberculous pneumonia, showed immediate clinical improvement in 8 days owing to decreased consolidation of the right lung and opening up of air-spaces. The improvement was not maintained, and death terminated a complicated pathology in which heart-failure, a spreading venous thrombosis, and associated œdema played a part.

Case 7, also an acute tuberculous pneumonia, was treated for 92 days and had a constant blood-streptomycin level of 6·0 μg. per ml. A temporary apparent improvement was not maintained.

In case 8 a generalised tuberculosis involving mediastinal glands, lungs, right sacro-iliac joint, loss of joint space between T8 and T9, and erosion of lower and outer part of L3 showed a slow improvement which did not appear to be modified by streptomycin.

Case 9, a tuberculous bronchopneumonia with a right pleural effusion, temporarily improved under streptomycin.

Case 10, one of three cases of miliary tuberculosis which showed clearing of the lungs, was adequately treated for 3 months. Between the 6th and 8th week of treatment there was a striking improvement in the patient's general condition, and spectacular radiological evidence of clearing of miliary tubercles was observed from the 7th week until death; the subsequent pathological and histological studies (*see addendum*) furnish evidence of healing of these lesions. It is of interest that, though the routine sample of C.S.F. taken on admission subsequently grew tubercle bacilli (one colony), the first sign of clinical meningitis was not elicited until the 66th day. After that the disease in the central nervous system pursued its inexorable course until death on the 89th day of therapy. Necropsy revealed an internal hydrocephalus from obstruction of the lateral and median foramina. Histological post-mortem evidence confirmed its tuberculous origin, though no organism was cultured. We decided to use heparin in the treatment of subsequent cases because we realised that this terminal state developed from *a* mechanical blockage originating in a pathological process which appeared to be no longer active.

In case 11 clearing of the miliary lung condition was first observed radiologically 4 weeks after exhibition of streptomycin, and appeared almost complete by the second month. This was followed later by the reappearance of coarse miliary tubercles. Early signs of meningitis detected 39 days after the start of treatment consisted of abnormal changes in the C.S.F., which began to return to normal after 3 weeks' treatment, and before heparin was given. In spite of the dose of streptomycin being increased to 2·4 g. daily the cervical lymph-glands continued to enlarge, caseate, and coalesce, confirming the clinical impression that the disease was again progressing. At necropsy, besides the old lesions, there were recent miliary tubercles.

Group II (Sulphetrone and Streptomycin)

In this group 6 patients received combined treatment. Cases 13, 14, and 17 were so gravely ill that no attempt was made to reach the optimal blood-sulphetrone level. In the case of chronic renal tuberculosis (case 16) the sulphetrone was excreted so rapidly in the urine that an effective blood level was not maintained. In cases 12 and 15 the blood-sulphetrone levels were satisfactory.

In case 12, a fibrocaseous pulmonary tuberculosis in a toxic and acutely ill patient with apparently low resistance, the hectic temperature and intoxication were modified after sulphetrone. During the combined course of sulphetrone and streptomycin the weight increased, the E.S.R. fell, and the previously positive sputum became negative. The acute lesion became chronic. Improvement was not maintained on withdrawal of the drugs, and collapse therapy was necessary.

In case 13, a chronic fibrocaseous pulmonary tuberculosis with cavitation, two phases were seen during the combined course of streptomycin and sulphetrone. In the first period of 6–8 weeks there was clinical and radiological improvement, with negative sputa, and the *infiltration* appeared to be halted. The second phase began suddenly and was characterised by rapid deterioration, both clinically and radiologically. At necropsy there was evidence of a breakdown of the patient's defences, leading to a progressive virulent infiltration.

Case 15 was a hæmatogenous pulmonary tuberculos not proved bacteriologically, in a Mantoux-positive chil aged $6^1/_2$ years, whose *father suffered* from open tube culosis. Radiography gave a picture of coarse " chronic miliary tuberculosis of the lungs. There were enlarg mediastinal glands. With adequate blood-sulphetro and blood-streptomycin levels the clinical conditi improved and serial radiograms showed a gradu regression of coarse miliary tubercles. A month aft withdrawal of both drugs there was a new phase pyrexia, and radiography showed much enlargement the left lung root, collapse of the left subapical segme enlarged left bronchial glands, and a " hilar flare." T condition was later controlled with sulphetrone.

The case of renal tuberculosis (case 16), which h showed *a considerable diminution* of the numbers organisms excreted on a previous course of sulphetro was unaltered by combined therapy.

In case 17, the severe spinal caries with chylous effu in the right pleural cavity, lung mottling, and pericard effusion showed consistent improvement, which w maintained. There was sputum reversal, and the E.S. and temperature returned to normal. The lungs beca substantially clear. The improvement was probab greater than would have been expected from sulphetro alone.

TOXICITY OF STREPTOMYCIN

The interesting fact that the streptomycin suppli *by the Wellcome Foundation caused only trivial* to manifestations has been previously reported (Madig et al. 1947). That the freedom from histamine-li impurities, pressor bases, and antidiuretic substanc which characterised this material was not the sole reas is shown by the persistence of toxic signs when strept mycin from other sources has been used. Thus, in clinical trial of streptomycin of 95% purity in 17 case renal and hæmatological toxic effects were found (F rington et al. 1947) which McDermott (1947) believed t be due to the streptomycin itself. No symptoms vestibular dysfunction or impairment of hearing we noted in our small series, though the intrathecal dose 0·2–0·4 g. daily, were higher than those usually give and the intramuscular dose, 1·2–2·4 g. daily, was withi the incriminated range.

Temporary pain on injection, much of which was du to the injection of hypertonic solutions, was occasionall observed. The inorganic content was such that strepto mycin 0·2 g. dissolved in 18 ml. of distilled water ga an isotonic solution. Two patients had 0·4 g. in 4 ml for long periods by slow intrathecal injection with onl temporary pain, which could be minimised by dilutio and slow injection, and aggravated by concentration o rapid injection. The volume of C.S.F. withdrawn befor injection did not affect the severity of the pain.

A temporary pleocytosis in the C.S.F., similar to that recorded by McDermott (1947), was observed in case 5, 10, and 11 accompanied by signs of an acute increas in generalised meningeal irritation, lasting in case 11 for 24 days, and in cases 5 and 10 in a subacute form during the course of intrathecal injections. The onset of pleocytosis, mainly polymorphonuclear, and the acute meningeal irritation (case 11) coincided with the start of intrathecal injections. The pleocytosis reached a maximum in 3 or 4 days with cell counts of 8200 (polymorphs 66%), 1040 (polymorphs 72%), and 1280 (polymorphs 90%) per c.mm., compared with 25 (no polymorphs), 226 (polymorphs 49%), and 60 (polymorphs 90%) per c.mm. before intrathecal therapy.

A moderate mental confusion developed in case 5, but there was no evidence to incriminate disease or drug in no instance did delirium or major mental disturbance appear. The attitude of the patients to repeated lumbar puncture was one of cooperation, in spite of the unavoidable discomfort and occasional subsequent pain.

Signs of irritation of peripheral nerve-roots were seen in cases 5 and 11, and pain on pressure over the sciatic nerve, hyperalgesia and loss of tendon-reflexes referable to the site of injection, and pain over the sacrum in case 5. These signs resolved after withdrawal of the streptomycin.

After repeated injections, piercing the meninges caused acute local pain in cases 5 and 11. Acute cramp-like pain in the distribution of the sciatic nerve at the site of injection and lasting about 5 min. was noted in cases.

The neck-rigidity, opisthotonus, and root signs reported in case 5 decreased on trial omission of the streptomycin and reappeared on its re-exhibition. At the end of the course of streptomycin the signs quickly disappeared; the cytology and chemical pathology reverted to normal more slowly.

Necropsy of the spinal cord in cases 1, 10, and 11 revealed a local non-specific meningitis.

Heparin 2 mg. injected in the streptomycin solution showed no local or systemic toxicity.

DEVELOPMENT OF RESISTANCE TO STREPTOMYCIN

Strains of tubercle bacilli isolated before and after therapy were tested for sensitivity to streptomycin. Except in the 4 cases of meningitis and the case of acute miliary tuberculosis, from which no organisms were recovered before therapy, all 12 strains fell within the range of sensitivity of 0·25–0·5 µg. per ml. of streptomycin base. By comparison at the same time the laboratory human strains H37 and CN844 were sensitive at 0·5 µg. per ml., and the bovine strain CN809 at 1·5 µg. per ml. In 6 of the 7 cases from which the organism could be recovered immediately after 3 months' therapy there was a well-marked increase in resistance (see table). The test medium was Long's synthetic medium to which had been added 2% agar, 0·025% lecithin, and 0·005% 'Teepol.'

SENSITIVITY OF STRAINS OF TUBERCLE BACILLI BEFORE AND AFTER STREPTOMYCIN TREATMENT

Case no. ..	5	7	9	10	11	12	13	14
Before (µg./ml.)	0·5	0·5	0·5	0·5	0·5	0·5	0·25	0·5
After (µg./ml.)	25	64·0	—	0·5	12·5	4·0	1·2	12·5

Tests for sensitivity both before and after streptomycin revealed that growth was stimulated by streptomycin at a concentration just too low to inhibit it. This concentration was commonly 0·25 µg. per ml. before and after treatment and was independent of the composition of the media, being observed also with those of Corper, Petragnani, and Dubos and Davis (1946).

The clinical and histological evidence focused attention on the contrast between the ineffectivity of streptomycin in established phthisis and the healing of the young lesions of miliary tuberculosis. In an attempt to clarify this behaviour of streptomycin we carried out the following experiments in vitro.

A 14-day culture of H37 strain of tubercle bacilli of human origin grown on Petragnani slopes was washed from the slopes, lightly shaken with stainless steel balls, washed with saline, resuspended in isotonic saline to give a concentration of 0·5 µg. per ml., and stored at 37°C for 24 hours. It was next exposed to streptomycin in concentrations of 10,000, 1000, 100, 10, and 1 µg. per ml. for 24 hours, 10 days, 14 days, and 30 days before being reinoculated on to Petragnani slopes. At 24 hours no concentration of streptomycin inhibited the subsequent growth of the bacilli; after 10 days concentrations of 100, 1000, and 10,000 µg. per ml. inhibited growth; and after 14 days 10 or more µg. per ml. inhibited growth—a position which remained unchanged after 30 days.

We interpret these results to mean that streptomycin is not bactericidal.

In a second experiment the same culture of tubercle bacilli 0·5 µg. per ml. was immediately—i.e., without being stored for 24 hours at 37°C—sown on to solid Petragnani slopes containing various concentrations of streptomycin; the tubercle bacilli did not grow at concentrations above 0·5 µg. per ml. Similar results were reported by Middlebrook and Yegian (1946).

DEMONSTRATION OF VIABLE TUBERCLE BACILLI

We found it difficult to demonstrate viable tubercle bacilli in the body fluids of about half the patients treated with streptomycin. During periods of clinical improvement, and when many acid-fast bacilli were demonstrable in direct or concentrated smears, adequately controlled cultural methods repeatedly failed. That the difficulty is not entirely due to the lack of a specific reversal agent in the media is suggested by the fact that the tubercle bacilli isolated by animal inoculation at the same time appeared to be of low virulence to guineapigs. Thus, in cases 5, 9, 13, and 17 the inoculated guineapigs lived more than 6 months and, when killed, showed typical generalised tuberculosis.

DISCUSSION

Observers mostly agree that human and bovine strains of tubercle bacilli are inhibited from reproduction on favourable media in vitro by concentrations of streptomycin base ranging from 0·25 to 1·5 µg. per ml. Since there is no difficulty in maintaining a constant concentration in blood and C.S.F.—but not in brain substance (Baggenstoss et al. 1947)—of many times this amount, there is a logical experimental basis for the clinical findings.

The possibility must be considered that in the 4 cases of uncomplicated meningitis the disease and its resultant changes were too well established to respond to chemotherapy. Only case 1 appeared to show a temporary modification of the usual course. Certainly chemotherapy cannot be expected to influence, for example, the mechanical blockage of the foramina which is a terminal hazard in tuberculous meningitis. In this connexion it is regrettable that the apparent therapeutic value of heparin (see below) had not been observed at this time.

A recovery is recorded in a case of proved tuberculous meningitis complicated by extensive fibrocaseous pulmonary tuberculosis (case 5). For 62 days, during which large doses of streptomycin were given intrathecally, the concentration in C.S.F. was at least 24 µg. per ml. for the first 16 days, and thereafter at least 82 µg. per ml. During the last 25 days 2 mg. (260 I.U.) of heparin was given intrathecally daily. No evidence is offered here that these large doses of streptomycin are necessary, and the combination of smaller doses with heparin may be preferable.

The extensive healing of the miliary tubercles in cases 10, 11, and 15 was in striking contrast with the lack of healing in the progressive cases 6, 7, and 13. Not only did the serial radiograms show regression of the fine miliary tubercles in cases 10 and 11, but there was also complementary post-mortem pathological and histological evidence. In the uncomplicated picture presented by case 10 successful repair was far advanced and only minute inflammatory foci, containing no bacilli, marked the original tubercles. Though in case 11 a second phase was superimposed on the original lesion, the picture was identical. In striking contrast is the evidence of progressive disease furnished in cases 6 and 13 by the clinical, radiological, and necropsy records.

The explanation of the different effects of streptomycin must be sought in the different nature of the two pathologies. It might be supposed that the strains of tubercle bacilli, shown here to be originally equally susceptible to streptomycin, would suffer a common fate when exposed to apparently identical chemotherapy; but this is not so. Under the cloak of "apparently identical chemotherapy," very different forces are brought to bear on the tubercle bacillus. In miliary tuberculosis of the lungs arising from a hæmatogenous spread, bacillary foci may be subjected to both natural resistance (phagocytosis, &c.) and the specific chemotherapy of streptomycin. Whether this combined operation is successful must largely depend on the efficiency of the tissue reaction.

It is legitimate to infer that in those lung conditions in which therapy failed the tissue reaction was ineffective. *A bronchogenic focus is a typical example*; here the first lodgment of the bacillus is followed by pathological changes which prevent tissue resistance, in particular blood-borne resistance, from playing an effective part.

It is convenient to speak of this aspect of the host-parasite relationship as environment. We are concerned here with only those aspects of environment which influence bacterial growth and reproduction and thus reflect changes in the metabolism of the bacillus. The experimental finding that only the dividing tubercle bacillus is susceptible to streptomycin clearly reveals the device (if self-preservation may be so called) by which the tubercle bacillus survives. The capacity of the resting tubercle bacillus to develop resistance by by-passing the particular metabolic process with which streptomycin interferes does not conflict with the known facts of its inexacting metabolic requirements.

In the present series, 6 strains of tubercle bacilli which could be isolated immediately on completion of the course had acquired a resistance to streptomycin which was between five and a hundred times as great as the initial resistance. It seems significant that two of the cases which acquired resistance (cases 11 and 13) showed a preliminary clinical improvement followed by rapid deterioration. The histological study of case 11 (see addendum) provides an interesting commentary on the clinical report. The "type-I reactions" are healed tubercles in which no bacteria can be detected; they correspond in time to a phase of clinical improvement and radiographic evidence of clearing of the miliary picture; they also correspond in time to the isolation of a strain of tubercle bacillus susceptible to 0·5 μg. per ml. of streptomycin. The "type-II reactions" are young active tubercles without signs of repair and containing enormous numbers of fine acid-fast bacilli. The onset of this second phase corresponds to clinical deterioration, the reappearance of miliary tubercles seen on radiography, and the isolation of a strain resistant to 12·5 μg. per ml. of streptomycin. Case 13 showed clinical and radiological evidence of improvement for 6–8 weeks and subsequently a phase of rapid deterioration. Once again the second phase was associated with an increase in resistance, though not a very great one.

Both the terminal clinical phases and the necropsy findings in cases 11 and 13 emphasise that the deterioration was associated with unrestrained aggression by the tubercle bacilli. Case 11 at all stages showed lymphatic involvement but in the terminal state illustrated complete and gross tuberculosis of the lymphatic chain associated with enormous numbers of tubercle bacilli. Case 13, originally a low-grade infection, in its terminal stages showed overwhelming infiltration, progressing to empyema with erosion of the intercostal muscles.

The experimental observation, that streptomycin in a concentration just too low to inhibit the growth of tubercle bacilli stimulates growth, appears to have an added significance in the light of these observations. The fact that the optimal inhibition by streptomycin is exerted on the dividing cells of a sensitive strain no longer constitutes an embarrassment to a resistant strain.

The remarkable increase in resistance in strains of tubercle bacilli recovered from cases other than miliary tuberculosis is in contrast with the animal experimen in which resistance was not developed during a simil period of chemotherapy (Brownlee and Kennedy 1948 *a fact which emphasises the important effect of enviro* ment on the metabolism of the bacilli. Whether simil changes in metabolism are sufficient to explain t difficulties encountered in recovering the organism culture and by animal inoculation after streptomyc therapy is worthy of further inquiry.

The experimental evidence for the synergism of sulph trone and streptomycin is strong (Brownlee and Kenne 1948b); but the clinical evidence, owing to the natu and limited number of the cases, does not provide clear-cut answer. The impression persists, however, th the cases treated by combined therapy responded mo favourably than they would have done on either dr alone. We are convinced that the status of both dru justifies a clinical trial of their combined use in milia tuberculosis of the lungs.

For tuberculous meningitis to be treated successfully local chemotherapy, it seems essential that the ca should be treated early. Any means which can be fou to prevent blocking of the median and lateral forami should be adopted; our experience suggests that t daily intrathecal injection of 2 mg. (260 I.U.) of hepar may prove effective. Our experience suggests that milia tuberculosis of the lungs may be successfully treat but that generalised miliary tuberculosis should presumed in these cases and intrathecal thera instituted.

We believe that the systemic exhibition of strept mycin is contra-indicated in the presence of chron lesions of lungs or lymph-nodes, because it may stim late resistant strains to rapid reproduction. The u of the drug is justified in tuberculous meningitis an miliary tuberculosis however, since they do no respond to any other treatment.

SUMMARY

In 17 cases of tuberculosis affecting different orga parenteral streptomycin was given for periods of betwe 13 hours and 3 months. The intramuscular four-hour dose of 0·2–0·4 g. of streptomycin base gave blood leve of 6–16 μg. per ml. The intrathecal dose of 0·2–0·4 g injected once daily, gave C.S.F. levels of 3–80 μg. per ml after 24 hours.

In 6 of the 17 cases sulphetrone by mouth was als given, leading to a blood-sulphetrone level of 7–8 mg per 100 ml. in 2 cases, and 2–4 mg. per 100 ml. in 4 cases

The toxic manifestations were trivial.

Of 4 cases of uncomplicated meningitis treated wit streptomycin only, 1 showed a temporary modificatio of the usual course of the disease.

Within the same group, 1 adult with proved tuberculous meningitis, complicated by extensive fibrocaseous pulmonary tuberculosis, recovered from the meningitis. The tuberculosis of the lungs did not improve.

In 3 cases of miliary tuberculosis of the lungs complicated by tuberculous lesions elsewhere there was radiological evidence of temporary progression and apparently total regression of the miliary tubercles. In 2 of these cases, in which necropsies were done, histological study showed that the original tubercles were healed or healing, and that acid-fast bacilli were absent. The third patient, who received sulphetrone also, is alive and well.

Except for 2 cases which became *clinically resistant*, the results in all the cases were equivocal; but those patients who received sulphetrone *also* appeared to do better.

All twelve strains of tubercle bacilli isolated before treatment were sensitive to streptomycin: all six strains isolated immediately after treatment were five to a hundred times more resistant. This is contrasted with experiments in animals.

In 2 cases (one of generalised lymphatic tuberculosis, other of chronic pulmonary tuberculosis) from strains resistant to streptomycin were isolated resistance developed during adequate therapy.

Difficulty was experienced in demonstrating by culture by guineapig inoculation viable tubercle bacilli body fluids containing numerous acid-fast bacilli obtained from about half the patients during omycin treatment.

The possibility of producing resistant strains which be stimulated to rapid reproduction contra-indicates exhibition of streptomycin in the presence of a onic lesion of lungs or lymph-nodes.

The intractable nature of tuberculous meningitis and iary tuberculosis justifies the use of streptomycin; y diagnosis is vital, and the combined use of ptomycin and heparin is suggested.

We wish to thank Mr. C. R. Kennedy and Mr. A. E. Fenton, the Wellcome Research Laboratories, for isolating and tifying the strains of tubercle bacilli, and testing their stance; and Mr. S. R. M. Bushby for most of the ptomycin estimations.

We gratefully acknowledge the coöperation and help of . J. F. Hackwood, medical superintendent, and his staff the County Hospital, Farnborough, and the nurses who erfully shouldered the additional burdens of round-the-k nursing at a time when staff depletions were heavy.

We are indebted to the Wellcome Foundation Ltd. for the pply of streptomycin and sulphetrone.

Histology of Typical Lesions after Streptomycin

(PROF. G. PAYLING WRIGHT)

The necropsy material in two fatal cases (11 and 10) was studied histologically to determine the tissue changes developing in cases of tuberculosis that had undergone protracted treatment with streptomycin.

CASE 11

In the lungs, liver, and kidneys two quite distinct types of reaction are present. Both are probably of a miliary tuberculous nature. The first, whose tuberculous ætiology might otherwise be in doubt, closely resembles that found in case 10, who is known to have had miliary tuberculosis. The second, though histologically atypical, contains very large numbers of acid-fast bacilli, morphologically like tubercle bacilli, in every characteristic lesion.

Type-I Reaction.—These lesions are small ovoid nodules, 400–600 μ long, lying irregularly in the affected organs regardless of their pre-existing normal structure. Fibroblasts are the most common cells in these lesions, many of which also contain some histiocytes and plasma cells. Most of the nodules are vascularised by small blood capillaries. No giant cells or typical epithelioid cells are present in any of the nodules, nor do any of them show signs of caseation. Gland-like remains of alveoli, such as are often found in areas of fibrosis in lungs, are occasionally present in and about the nodules. Between the cells of the nodule, and usually separating them fairly widely, are small irregular structureless masses which stain a light pink with eosin and a deeper pink with van Gieson's stain. From its morphology and staining reactions, this material is almost certainly recently deposited collagen. No acid-fast bacilli are present in any nodules of this type.

Type-II Reaction.—These lesions have an entirely different character and structure from those of type I, though, like them, they are distributed irregularly throughout the organs affected. They are roundish, and usually range from 200 μ to several millimetres in diameter; occasionally they are even larger. They are formed almost entirely of vast numbers of closely packed, degenerating, and dead histiocytes, though a few plasma cells are occasionally present near their margins. Only in the spleen are typical tubercles, with Langhans-type giant cells, found, and here they are fairly numerous. In the larger typical lesions the central parts are beginning to caseate, though the presence of much basophilic nuclear debris shows that this change only began shortly before death. All type-II lesions contain enormous numbers of fine acid-fast bacilli. There are no signs of any fibrous tissue reaction round the margins or in the vicinity of any lesions of this type.

Lesions in Individual Organs.—*Lungs:* numerous foci of both types distributed throughout the section. *Ileum:* active tuberculous lesions in both the submucosa and subserosa. *Liver:* one large and many small recent lesions; some of the older variety. *Pancreas:* nothing abnormal seen. *Spleen:* many lesions of both types. *Kidney:* one large recent and three old lesions. *Prostate:* nothing abnormal seen. *Thyroid:* many large recent lesions. *Brain:* very little cellular reaction in subarachnoid space; many acid-fast bacilli present.

CASE 10

In many of the organs small foci are present which have the following histological structure, and closely resemble the lesions of type I in case 11. The lesions are nodular, roughly 200–400 μ in diameter, and are distributed irregularly in the organs regardless of their pre-existing normal architecture. They exhibit various proportions of cells and intercellular material, though in most nodules the latter much predominate. All contain a large proportion of fibroblasts and smaller proportions of other types of cell. Histiocytes can be readily recognised from the dust particles in their cytoplasm. Some nodules contain many lymphocyte-like cells. No giant cells or typical epithelioid cells are present in any nodule. Many of the foci are vascularised by fine blood capillaries. All the nodules contain many small irregular masses of intercellular material, which stain pink with eosin and bright red with van Gieson's stain, and are thus almost certainly collagen. The amount of this material and the number of lymphocytes in the nodules appear to vary inversely. All evidence of the previous architecture of the tissues seems to have disappeared from these nodules, except in the lungs, where small gland-like acini, the remains of former alveoli, are sometimes discernible. No acid-fast bacilli are present in these lesions.

The lesions give the impression of being minute inflammatory foci from which the bacilli have disappeared and in which the reparative changes are far advanced though not yet complete. They may thus be regarded as indicating successful defence and reparative healing.

Lesions in Individual Organs.—*Heart:* nothing abnormal seen. *Lungs:* many characteristic nodules; some intra-alveolar œdema. *Liver:* some typical nodules, differing only from the above reaction in being rather smaller and less cellular; their distribution is irregular. *Pancreas:* nothing abnormal seen. *Spleen:* many typical nodules. *Adrenal:* nothing abnormal seen. *Meninges:* a section from the interpeduncular space shows a characteristic tuberculous reaction, with some giant cells and many epithelioid cells and lymphocytes; some of the larger foci show early caseation; no acid-fast bacilli found.

COMMENT

Though both the type-I and the type-II lesions are almost certainly of a generally disseminated miliary tuberculous nature, they present such different histological features and, by inference, such a different host-parasite relationship, that it is difficult to reject the view that they resulted from separate bacteræmias with bacilli of very different grades of virulence. The alternative explanation—that the resistance of the host had changed considerably between the two phases of dissemination—seems less probable in view of the comparatively short interval which, from the clinical history of the patient, appears to have separated the two events.

In type-I lesions all the many foci show every sign that the local infection has been successfully countered, for in all the nodules the processes of organisation and fibrosis are almost complete. These lesions closely resembled those described by Baggenstoss et al. (1947) for their case 3. In type-II lesions, which appear to have resulted from a more recent dissemination of bacilli, the foci seem to have been extending rapidly at the time of death. The lesions of this type might correctly be described as acute histiocyte abscesses. Except for some foci in the spleen, none of the lesions of either type resembled a typical miliary tubercle.

PRIMARY SPLENIC ABSCESS

Michael Gelfand
M B. Cape Town, M R C.P., D.M.R
GOVERNMENT MEDICAL OFFICER, NATIVE HOSPITAL,
SALISBURY, SOUTHERN RHODESIA

Wallace (1922), of Northern Rhodesia, appears to have been the first to describe primary splenic abscess in the African. He saw 49 cases in Broken Hill within a few years and gave an accurate account of its clinical features. The illness ran a relatively short pyrexial course with, as a rule, much constitutional disturbance. Wallace was not certain of its cause. He did not find the amœbic organism in any of his cases, and surface culture made on agar slopes at operation or post mortem never showed any growth. Wallace excluded various fevers, including relapsing, undulant, and typhus fevers, and syphilis. In some cases he recovered a spore-bearing bacillus, which he held responsible for the gas he found in the abscess.

In some of the cases reported by Wallace the condition of the spleen macroscopically resembled multiple infarction, though in most of them the entire splenic tissue was replaced by pus. I have reported sporadic cases in Mashonaland, the cause of which I could not determine (Gelfand 1947), and have suggested that splenic abscess may be a late stage of infarction in which the total blood-supply of the spleen is lost after thrombosis of the splenic vein, liquefaction with colliquative necrosis resulting. In this respect it is interesting that Wallace believed splenic abscess to be a manifestation of influenza, the causal bacillus producing the thrombosis in the spleen with subsequent softening, which was followed by invasion by gas-forming organisms from the intestine.

Wallace observed that many of his patients later developed thrombosis of the leg veins, with swelling and œdema of the affected limb. He reported inexplicable cases of cerebral and intestinal thrombosis. It is probable that these cases which Wallace encountered had idiopathic thrombophlebitis. This was later recognised as such by Fisher (1941) working in the copper belt, Northern Rhodesia.

In the case I previously reported (Gelfand 1947) a large gas shadow was seen radiographically in the abscess. In the present case a very large gas shadow is also visible. Efforts to demonstrate the cause of the gas shadow, such as gas-producing bacillus, proved unsuccessful.

CLINICAL PICTURE

Though the ætiology of primary splenic abscess remains obscure, the illness as a rule runs a characteristic course, and the diagnosis can usually be determined with little difficulty. The disease is generally seen in relatively young adults aged 18–35. My patients so far have all been males, though Wallace (1922) reports that 3 of his 49 were women. All of mine have insisted that their health was good before the onset.

The illness begins with abdominal pains, worst over the left hypochondrium. Simultaneously the patient develops pyrexia, which may be moderate or severe. He feels ill, and as a rule stops working. Soon the spleen begins to enlarge and, after a few days or a week, he becomes aware of a swelling over the splenic This swelling rapidly increases in size, and a few later can be seen as an abdominal tumour.

The tumour is tender, though later the becomes less and may indeed be absent. The of the swelling follows that of a splenic tumour. I enlarges downwards and inwards, towards and past the umbilicus. Unless one is observant, the may be labelled as one of ascites, for the abdominal wall may be much distended by the There is usually, but not always, a tympanitic note the tumour. Wallace, who placed much reliance this sign, wrote: "An abdominal tumour which sponds in position and shape to an enlarged spleen which is tympanitic on percussion is, I consider, nomonic of splenic abscess." A fluid thrill may felt. In the case reported below, a succussio was clearly audible on turning the patient som rapidly on to either side. The blood usually shows moderate leucocytosis.

Generally the patient will appear for treatment largely because of the abdominal swelling, which reaches its maximum within a fortnight. After this it remain constant in size. It would be interesting to know how long a patient with such a large collection of pus may continue without serious consequences. One young adult native male had an acute swelling which reached its greatest extent within two weeks, and I saw him in apparently good health four years later, with an enormous splenic tumour. According to Wallace, the tumour, if left untreated, usually ruptures into the abdominal cavity. This possible event I have not so far encountered, though it appears the most obvious complication.

DIAGNOSIS

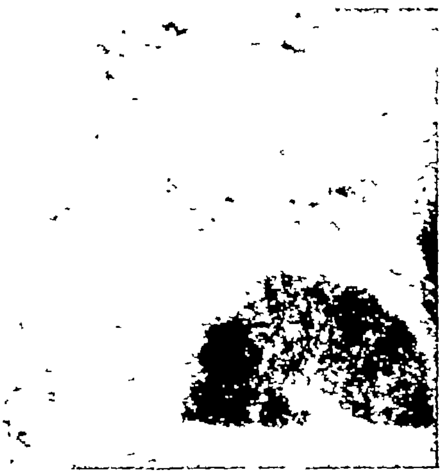
As a result of the gross enlargement of the spleen, the left dome of the diaphragm is considerably raised, producing a distinct dullness, with a poor air entry or absent breath sounds, posteriorly at the base of the left lung. Thus the condition may easily be mistaken for pneumonia or an empyema in this region.

The elevation of the left dome can best be demonstrated radiologically. As a result, too, the heart is displaced to the right side (see figure). In my last three cases gas shadows were demonstrable. Wallace (1922) believed that gas-forming organisms were responsible for the gas he found in the abscess at operation. I have not, so far, been able to isolate any such organism. The radiological appearance of the gas shadow beneath the much elevated left dome of the diaphragm, with a fluid level below, might be attributed to the gastric gas shadow normally seen on radiography. This is possible but very unlikely, since the stomach lies beneath the spleen, and therefore, with so great a splenic enlargement, one would expect it to be displaced downwards and medially.

Thus, radiologically, there are three points which make the diagnosis of primary splenic abscess almost certain:

(1) Elevation of the left dome of the diaphragm
(2) Contralateral displacement of the heart.
(3) A gas shadow below the dome and above a distinct fluid level. So large a gas shadow with a fluid level may be mistaken radiologically for a hydropneumothorax or an eventration of the left dome of the diaphragm.

After positive radiological proof has been obtained the diagnosis is confirmed by aspiration. The pus is chocolate brown or reddish-brown and very like anchovy-sauce pus; but this colour is probably derived from the deep brown splenic tissue. Microscopical examination reveals amorphous material with little structure and few or no pus cells. Culture is usually sterile. Amœbæ are not demonstrable.



X-ray photograph of chest showing elevation of left dome of diaphragm almost to level of sixth intercostal space, with large gas shadow and fluid level below, and heart displaced to right.

In the present case a careful effort was made to isolate the gas-producing organism in the pus, but this proved unsuccessful. There was no history suggesting amœbic disease. Amœbic abscess of the spleen has previously been reported, but the course in primary splenic abscess is quite different. This applies particularly to its rapid onset and the appearance of an enormous tumour within a short time. Emetine is without effect.

TREATMENT

The treatment of primary splenic abscess recommended by Wallace is surgical drainage. So inflammatory a tumour cannot be removed, owing to the perisplenic adhesions. Secondly, the tumour is so enormous that successful removal in toto is rendered impossible. On the other hand, aspiration is often disappointing: owing to the chronically inflamed capsule which is left behind, a pus-discharging sinus usually persists many months.

CASE-RECORD

An adult native male, aged about 27, was admitted to the Native Hospital, Salisbury, on June 29, 1946, his home lay in the Mrewa Reserve, about 55 miles away. He was intelligent and gave a coherent account of his illness. He was apparently in very good health until a week before admission, when he had noted pain in the splenic region and a mass which had rapidly increased in size. The mass had reached its present size in about seven days. Otherwise he made little complaint, there being no cough, headache, vomiting, or history of hæmoptysis. There was no previous history of dysentery, diarrhœa, or any disturbance of micturition.

On examination he was poorly nourished and thin. Conjunctivæ well coloured. Corneal opacity in right eye. No icterus. Tongue furred, but edges of good colour. Gums not spongy. Well-marked signs of pellagra over legs, forearms, and trunk. No œdema or adenopathy. Fingers not clubbed. Neck veins slightly distended.

Temperature on admission 101·6°F, and this figure was maintained to a greater or less extent both before and after the operation. Apex-beat about 1 in. within left nipple line. *Systolic murmur present, best heard over mitral area.* Dullness both anteriorly and posteriorly in lower zone of left lung. Scattered rhonchi audible in rest of left lung and in right lung.

Blood-count: red cells 4,310,000 per c.mm., Hb 67%, colour-index 0 77, white cells 17,300 per c.mm. (neutrophils 37%, lymphocytes 52%, monocytes 9%, eosinophils 2%).

A large fluctuating swelling occupied the left hypochondrium and the epigastrium. *Umbilicus displaced downwards.* Lowermost limits of swelling extended to about 2 in. to right of and just below umbilicus. Lower edge of swelling could be fairly easily defined. Mass slightly tender; fluid thrill easily elicited. On moving the patient on to either side a succussion-splash was also audible. Mass resonant to percussion. Both flanks dull. Whole abdomen distended, superficially resembling ascites.

Radiography of chest showed left dome of diaphragm to be considerably elevated, reaching up to sixth intercostal space. Beneath dome was a gas shadow about $3^1/_2$ in. high and about 5 in. across. Below gas shadow was a dense shadow showing a fluid level. Heart displaced to right (see figure).

Wassermann reaction of blood negative. No parasites found in stools. Urine contained albumin and numerous leucocytes.

On the 30th a diagnostic aspiration was performed and the diagnosis of splenic abscess confirmed. The pus was of an anchovy colour. No organisms were isolated on culture of the pus, and no amœbæ were discovered. The cytology of the pus revealed nothing characteristic, only a few scattered pus cells being present.

Treatment and Progress.—The case was referred to Mr. E. Barnett, who drained the abscess on July 3. At least 14 pints of watery chocolate-coloured pus was evacuated. Two drains were inserted through the abdominal wall, one laterally and the other anteriorly. After the operation a course of emetine was administered (gr. 1 daily for ten days by intramuscular injection) but without any significant effect on the discharge.

The patient made satisfactory progress in hospital except that pyrexia up to 101·5°F continued in an irregular manner and the pus continued to discharge through the anterior drain. His general condition, however, was much improved. He was discharged from hospital in the middle of August and returned to the clinic in the Mrewa Reserve. Inquiries made at the clinic a month later revealed that the discharge from the abdominal sinus was still fairly profuse.

SUMMARY

A case of primary splenic abscess in a young African adult is described.

The chief radiological signs of the disease include elevation of the left dome of the diaphragm; a large gas shadow, with a fluid level, beneath the left dome of the diaphragm; and contralateral displacement of the heart.

The clinical features of primary splenic abscess are described.

My thanks are due to Dr. R. M. Morris, medical director of Southern Rhodesia, for his kind permission to publish this paper.

ANTITHYROID ACTIVITY OF ERGOTHIONEINE IN MAN

E. B. ASTWOOD
M.D.

MALCOLM M. STANLEY
M.D.

From the Joseph H. Pratt Diagnostic Hospital and the Department of Medicine, Tufts Medical School, Boston, Massachusetts

With comments by

MR. A. LAWSON, PH.D., and PROF. C. RIMINGTON

THE finding of Lawson and Rimington (1947) that ergothioneine has an antithyroid effect of a magnitude similar to that of thiouracil when tested in rats is of great interest, as has already been pointed out (*Lancet* 1947). The natural occurrence of this substance in blood suggested that it might be involved in the regulation of thyroid function. Also, since the quantity in the blood is said to depend partly on the diet (Eagles and Vars 1928), it seemed possible that this substance might be important in the genesis of simple goitre. It was therefore desirable to test the antithyroid effect of the compound in man. A simple method for doing this, using radioactive iodine, has recently been described (Stanley and Astwood 1947).

The ergothioneine was isolated from commercial powdered extract of ergot (Lilly) by the method of Pirie (1933). It was purified by recrystallisation from water as the hydrochloride and converted to the free substance by neutralisation of an alcoholic solution of the hydrochloride with pyridine; the precipitated free ergothioneine was dried in vacuo over sulphuric acid. The hydrochloride melted at 210–211°C (uncorrected), and the free substance at 260–265°C (uncorrected) with decomposition. Analysis showed—

Calculated for $C_9H_{15}O_2N_3S$: C, 47·17 ; H, 6·59 ; N, 18·33 ; S, 13·98.

Found : C, 47·14, 46·89 ; H, 6·36, 6·51 ; N, 19·05, 18·87 ; S, 14·17, 14·28.

The intensity of the colour produced with Hunter's reaction (Hunter 1928) was in agreement with the artificial phenol-red standard solution described by Hunter. The substance gave a positive test with Grote's reagent (Grote 1931). After addition of the material to whole blood, so that the final concentrations were 2 to 12 mg. per 100 ml., analysis by Hunter's method, after deproteinisation with tungstic acid, revealed an average recovery of 60%. Attempts to determine the material in whole blood after its administration were uniformly unsuccessful, indicating that concentrations in the blood of more than 0·05 mg. per 100 ml. were not achieved with the doses used.

Ergothioneine was administered by mouth to five normal persons in doses of 50, 200, and 400 mg., and intravenously in doses of 120 and 400 mg. Fig. 1 shows that each of the tests with radioactive iodine on these persons was completely negative. Fig. 2 shows the results obtained in four normal persons: one untreated; one injected intravenously with 1 g. of sodium thiosulphate, a substance said to be beneficial in thyrotoxicosis (Biancalana 1947); and, for purposes of comparison, one given 10 mg. of mercaptoimidazole, a potent antithyroid agent, and one given 50 mg. of methylthiouracil.

In view of these unexpected results ergothioneine was tested in rats by the usual method of feeding in the diet (Astwood et al. 1945), and by the method of Lawson and Rimington (1947) of daily subcutaneous injections. The daily injection of as much as 5 mg. to rats weighing 50–100 g. exerted no significant effect on the weight or on the iodine content of the thyroid gland in ten days. Likewise, the feeding in the diet of as much as 0·03% of ergothioneine for ten days was completely without effect on the thyroid gland. Parallel experiments with small doses of thiouracil yielded the usual result.

To test the possibility that some other antithyroid compound closely related to ergothioneine might be present in the ergot extract, a crude preparation consisting of the entire cuprous ion-precipitable material was fed to rats for ten days. Each animal received a quantity of "ergothioneine" amounting to 20 mg. daily as determined colorimetrically. The weight and the iodine concentration of the thyroid glands remained unchanged. Similar tests with sodium thiosulphate administere subcutaneously in doses of 0·5 and 5 mg. twice dail or given in the diet in 1% concentration were entirel negative.

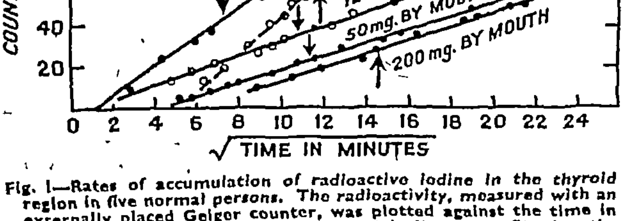

Fig. 1—Rates of accumulation of radioactive iodine in the thyroid region in five normal persons. The radioactivity, measured with an externally placed Geiger counter, was plotted against the time in minutes on a square-root scale, and straight lines were fitted to the points by eye. The arrows indicate the time when the ergothioneine was administered either by mouth or intravenously (I.V.), and the various doses expressed in mg. of the hydrochloride are shown. It is to be noted that no significant deviation from the predicted rectilineal curve of uptake was brought about by the ergothioneine.

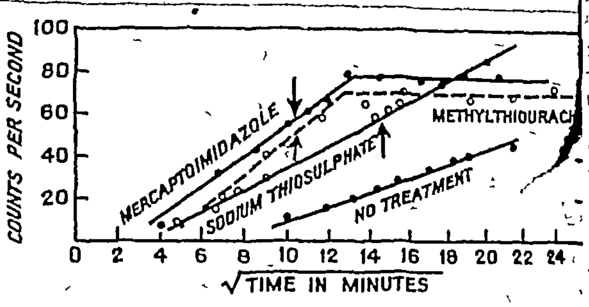

Fig. 2—The course of iodine accumulation in four normal persons shown for comparison with fig. 1. The usual straight-line course was observed in the untreated subject. The intravenous injection of 1 g. of sodium thiosulphate did not modify the course of iodine uptake. The administration of 50 mg. of methylthiouracil by mouth caused the iodine uptake to cease, and the inhibition lasted for four hours. Mercaptoimidazole in a single dose of 10 mg. by mouth completely inhibited the iodine accumulation; in this instance the effect lasted for twenty-four hours.

It was concluded that, by the methods used, th substance isolated from ergot extract, giving appropriat analytical data for ergothioneine, failed to exhibit a antithyroid effect in the human being, or in the rat, i the dosages employed.

B.Sc., Ph.D. Glasg.

C. Rimington
M.A., Ph.D. Camb., D Sc. Lond

Professor Astwood has kindly allowed us to read his communication with Dr. Stanley. We have some comments to make on their findings, and further observations to report.

Since our first publication (Lawson and Rimington 1947) we have obtained sufficient ergothioneine to carry out therapeutic trials in two patients with thyrotoxicosis. The drug was administered by intramuscular or subcutaneous injection at a level of 100 mg. of hydrated hydrochloride, equivalent to 79 mg. of ergothioneine base, per patient per day for fourteen days in one case and seventeen days in the other.

This amount was chosen as being roughly equivalent, from our previous rat tests, to the dose of thiouracil normally given by mouth to thyrotoxic patients in University College Hospital. In neither case was there any change in the basal metabolic rate or other sign of clinical response.

Much effort has been spent on the problem of the quantitative determination of ergothioneine in whole blood, plasma, and urine; but so far a reliable procedure has not been devised. Experience with the Hunter (1928) method quickly showed that, though satisfactory for solutions of pure ergothioneine, it was inapplicable to biological fluids. Recoveries of ergothioneine added to blood or even to blood filtrates were low and variable, and such losses were particularly great with plasma. Some, but not all, of the factors responsible for these irregularities have been detected.

Sullivan and Hess (1933) have used Folin's uric-acid reagent for the determination of ergothioneine in urine, but they were able to isolate only a small percentage of which this reagent indicated to be present. se of this method appeared to us unsafe until results be confirmed by a more specific procedure. Our ue, Dr. C. E. Work, has therefore adapted the que of paper-partition chromatography to the m in a roughly quantitative manner, details of h will shortly be published. This method, which the great merit of specificity, afforded figures for l urinary excretion of about 150 mg. of ergothioneine ly. In view of such a surprisingly high figure, it may be that the dosage level of 79 mg. used for our ats was totally inadequate.

Astwood and Stanley have apparently experienced same difficulty with the Hunter technique as we have, we do not understand their statement that blood-thioneine levels no higher than 0·05 mg. per 100 ml. e achieved with the doses they used in normal s. If this is the total ergothioneine they measured, less than 1% of the amount stated by Hunter to be nt in normal human blood.

Astwood and Stanley have also not observed a lowering the iodine content of the thyroid glands of rats dosed h ergothioneine by mouth or even by injection of amounts of the drug. This difference from our own ts we cannot at present explain.

There seems to be no reasonable doubt about the ity of the materials used. Our preparations, d in vacuo, afforded the following figures on lysis:

Preparation A: melting-point 112°C. Found: N, 15·87, S, 11·95, 12·08; Cl, 13·35, 13·33.

Preparation B: melting-point 112–113°C. Found: C, 39·85; H, 6·21; S, 12·25.

Theoretical: C, 40·76; H, 6·04; N, 15·82; Cl, 13·37; 12·05.

all experiments the material given was the hydrochloride.

When we first used the extraction method of Pirie (1933) without modification, we invariably obtained, ther with ergothioneine, a product which was inactive the rat test and appeared to be guanine. Guanine gives intense colour with the diazo reagent but no colour the gold-chloride test, and is free from sulphur. When method of extraction was modified, a good yield of thioneine was regularly obtained.

In constructing our reference assay curve for thiouracil by the rat method,* we noted that the line we obtained ting thyroid iodine to dose per kg. of body-weight log. scale) was displaced much to the left of that lished by McGinty and Bywater (1945). In other ds, the fall in iodine content of the glands from the an figure of the controls (about 58 µg. per 100 mg. of t weight) was some three or four times greater in our mals than in those of the Detroit workers. This erence may be due to differences in the iodine contents the basal diets, since Vanderlaan and Vanderlaan (1947) have shown that antithyroid drugs of the thiouracil pe do not lessen the power of the glands to concentrate dide from the blood, and that the residual level of dine determined in the glands of drug-treated animals resents mainly the inorganic iodide which these have taken up from the body fluids. McGinty and Bywater (1945) say they fortify their diet with 12 µg. of iodine per rat per day, given as potassium iodide. Our basal diet was unfortified. It is at present being analysed for iodine.

We also noted that, whereas thiouracil in doses of 2·5 mg. or more per kg. of body-weight brought the gland iodine of our animals to a minimum of about 5 µg. per 100 mg. of body-weight, even large doses of ergothioneine rarely lowered this beyond about 10–15 µg. per 100 mg. of body-weight. The reason for this difference is not clear.

Astwood and Stanley mention that they did not note any hyperplasia of the thyroid produced by ergothioneine. In our experience this was not pronounced (at 20 mg. per kg. of body-weight subcutaneously for fourteen days) but, we venture to think, unmistakable, as in the following example:

WEIGHT OF THYROIDS OF CONTROL AND ERGOTHIONEINE TREATED RATS DOSE 20 MG. PER KG OF BODY-WEIGHT SUBCUTANEOUSLY FOR FOURTEEN DAYS

—	Controls			Treated			
Body-wt. (g.)	166	144	145	151	171	157	173
Thyroid wt. (mg.) ..	13	11	13	15·5	20·5	17·5	16
Thyroid wt. (mg. per 100 g. of body-wt.) ..	7·83	7·65	8·97	10·25	12·0	11·15	9·25

In view of the findings of Astwood and Stanley, we are repeating our experiments on rats to discover the cause of our disagreement. A consideration which has not escaped us is the possibility that ergothioneine (R.SH) may suffer oxidation to the disulphide (R.S-S.R) and we have reasons for thinking that an equilibrium may exist in vivo between these forms, thus accounting for many of the difficulties of quantitative determination. A disulphide form might have little or no antithyroid effect.

We are indebted to Messrs. Burroughs Wellcome & Co. for generously preparing 16 g. of ergothioneine hydrochloride from ergot, which enabled us to conduct the preliminary trials. The patients were under the supervision of Prof. H. P. Himsworth, Dr. W. R. Trotter, and Dr. M. E. Morgans, whom we wish to thank for their collaboration. We are indebted to Dr. R. E. Moore for the thyroid weights quoted.

WERNICKE'S ENCEPHALOPATHY SIMULATING DIABETIC COMA

F. AVERY JONES
M.D. Lond., F.R.C.P.
PHYSICIAN IN CHARGE OF DIETETIC DEPARTMENT, CENTRAL MIDDLESEX COUNTY HOSPITAL

V. C. ROBINSON*
M.B. Camb., M.R.C.P.
LATE PHYSICIAN TO THE HOSPITAL

HYPERGLYCÆMIA with Wernicke's encephalopathy has not been described before, and the case reported here closely resembled diabetic coma.

A man, aged 63, was admitted to hospital with a history that two weeks previously he had gone to bed with a septic corn on the left foot. The leg became red and swollen to the knee.

Three days before admission he became drowsy and refused food and drink. His wife said that his usual diet was: breakfast, bread and butter, tea; lunch, meat and vegetables; tea, bread and butter with jam or fish or meat paste, tea.

On Examination (in the casualty department).—A wasted dehydrated man, with a red glazed tongue, too apathetic to give more than a vague account of himself. The urine contained much sugar and albumin but no ketones. His left foot showed brown discoloration, with increased segmentation

---

* Our assays are conducted on immature rats weighing uniformly 45–55 g. as recommended by McGinty and Bywater (1945).

* Dr. Robinson died shortly after this paper was written.

Time	Blood-sugar (mg. per 100 ml.)	Insulin (units)	Intravenous fluid (litres)	Blood-pressure (mm. Hg)
12 noon	800	50 I.M. 50 I.V.	2 of normal saline, rapidly	Unrecordable
4 P.M.	1000	50 I.M. 50 I.V.	..	95
8 P.M.	1000	200 I.M.	..	110
12 midnight	750	200 I.M.	1 of plasma taking 2 hr.	70
3 A.M.	..	..	2 of 5 % glucose-saline	70
9 A.M.	..	..	2 of 5 % glucose-saline	115
12 noon	380	100 I.M.	..	110

pattern of the skin, and a septic corn on one toe. No cheilosis.

Progress.—He was admitted as a case of inanition but within twenty-four hours deteriorated to a restless comatose state, with irregular nystagmus and quick jerking movements of the face, neck, and arms. His breathing was irregular, jerky, and interrupted by short grunts.

Nervous System.—The limbs were rigid and the deep reflexes absent; Chvostek's and Trousseau's signs could not be elicited. The cerebrospinal fluid was under increased pressure but otherwise normal (total protein 0·05 g. per 100 ml.; Lange's test 00000000; lymphocytes 1, polymorphs 9, and red blood-cells 2380 per c.mm.). Feeding by mouth had been impossible, and the dehydration and emaciation were more striking. Peripheral failure was well marked, the blood-pressure being unrecordable and the extremities cyanosed.

Urine.—Catheter left in for incontinence. Urine contained much sugar and albumin, with pus cells and *Bact. coli*, but still no ketones; nor could any acetone be smelt in the breath. Blood-urea 114 mg. per 100 ml.

Diagnosis.—He was regarded at first as being in diabetic coma and not excreting ketones because of renal failure: but when blood examinations showed neither lipæmia nor ketones (Rothera) a hypothalamic vascular lesion was considered. Wernicke's encephalopathy was not diagnosed until the third day, when intensive treatment with vitamin-B complex was begun.

Further Treatment and Progress.—The treatment given and findings during the first twenty-four hours are shown in the accompanying table.

At 6 A.M. next day the blood-sugar was 150 mg. per 100 ml. and the patient was conscious enough to use the commoner expletives and take fluid by mouth. His general condition was much improved and dehydration less.

For the next fifteen hours his blood-pressure remained 110 mm. Hg and his general condition improved further, so that he could answer questions. *During this time he* vomited altered blood several times and passed several melæna stools. There was still slight nystagmus, but the other muscular movements had almost disappeared. T limbs remained rigid.

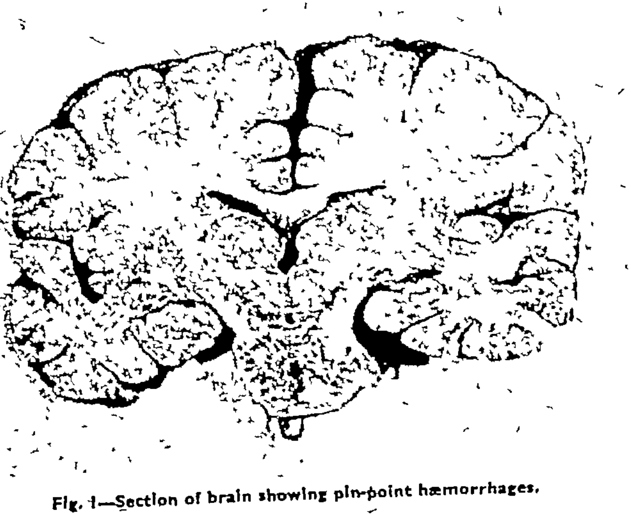

Fig. 1—Section of brain showing pin-point hæmorrhages.

He was given 500 mg. of ascorbic acid, 25 mg. of aneuri once, and nicotinic acid 100 mg. five times, all by injection.

At 9 A.M. next day the blood-sugar was 500 mg. per 100 m and he was given 50 units of insulin intramuscularly.

At 12 noon the blood-sugar was 300 mg. per 100 ml. T patient died two hours later of pulmonary œdema.

Necropsy Findings.—Emaciated body, œdema of lun heart normal except for some hardening of aortic valv bilateral pyelonephritis, normal pancreas.

Brain showed many small "flea-bitten" areas, mostly pons and subthalamic region (fig. 1). Corpora mammila were free, but fornix and anterior commissure showed sm hæmorrhages.

Histological examination showed gross irregular cap dilatation, small "ball" hæmorrhages (fig. 2) and also sm ring-shaped (fig. 3) hæmorrhages, and some areas of demye tion and perivascular necrosis. These changes are consiste with a diagnosis of Wernicke's encephalopathy.

COMMENTS

The clinical features correspond more closely to t nicotinic-acid-deficiency encephalopathy described Jolliffe et al.[13] and Sydenstricker[20] than to Wernicke encephalopathy. Besides the clouding of consciousne ocular disturbances, and peripheral neuritis, there w *cog-wheel rigidity of the extremities.* The distincti is probably a fine one, for the morbid anatomical ba is apparently identical. Campbell and Russell[5] sugg that Wernicke's syndrome and the picture described Jolliffe et al. differ in the intensity of the deficiency of aneurine and of nicotinic acid present.

Neither type has previously been described with hyperglycæmia, and two possibilities must be considered in the case described here—did the encephalopathy develop in a diabetic, or was the hyperglycæmia du to the injury of a hypothalamic area by minute hæmor rhages, corresponding to that produced in animals by Claude Bernard[4] by puncture of the floor of the fourth ventricle ?

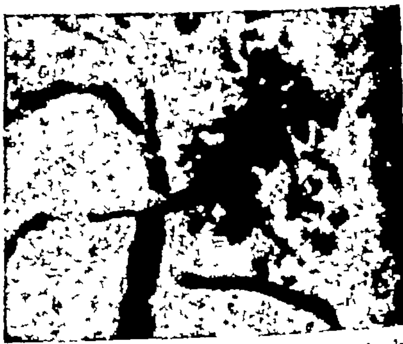

Fig. 2—Portion of brain under high power, showin typical "ball" hæmorrhage. (× 350)

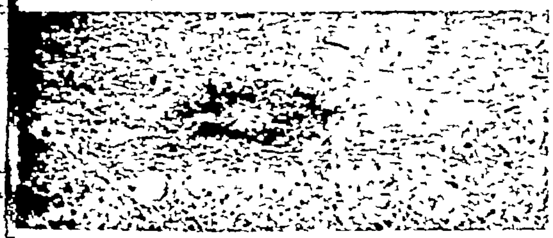
Diabetes seemed improbable, for an underweight patient with coma would certainly have had thirst and polyuria. The absence of ketones in the urine was not conclusive. Ketones may not be excreted if there is severe renal failure, and their absence may also be explained by an excess of β-hydroxybutyric acid with little acetone or aceto-acetic acid to give the colour reactions.[19] In this patient there was some impairment of the renal function (blood-urea 114 mg. per 100 ml.), and post mortem there was bilateral pyelonephritis, but the Rothera test was negative in the blood-plasma. The possibility of an unusual partition of ketones was not excluded. A further point against diabetes was the absence of lipæmia. The explanation favoured in this case is to attribute the hyperglycæmia to injury of the hypothalamic area by a minute hæmorrhage. It is of interest that there was considerable insulin insensitivity, 850 units being needed to lower the blood-sugar.

The previously reported cases of diabetic coma without ketosis[1–3 6–12 14–17 19 21] have been reviewed, but in only that of Evans 7—did it seem likely that a similar logy was responsible. Unfortunately in that case clinical data given were scanty and there were morbid anatomical findings.

This punctuate hæmorrhagic encephalopathy has ally been found associated with alcoholism or with es of the alimentary tract which have impaired the rption of food, and the lesions probably represent action to a vitamin-B-complex deficiency.

It is difficult to explain why this patient should have eloped an encephalopathy, but an acute deficiency may e been precipitated by the infection of the foot and ary tract causing increased demands on vitamin-B complex when perhaps no reserves existed. This mechanism s been described in patients after operation.[18]



1—Portion of brain under low power, showing typical "ring" hæmorrhage. (× 100.)

SUMMARY

A fatal case of Wernicke's encephalopathy is described h a blood-sugar level of 1000 mg. per 100 ml. but no . It is suggested that the hyperglycæmia was the lt of a minute hæmorrhage into the hypothalamus.

Our thanks are due to Dr. W. Pagel for his report on the ology, and to Dr. Richard Asher for his constructive icism.

. . . There can be little doubt that Surgery is facing further change in the relative emphasis placed on the component parts of its content. Science will increase, and scientifically based Technology will slowly replace Empiricism. There are certain to be changes in the organizational patterns formed by Hospital, University, and State These changes may be brought about by explosive forces in the restless external social order, or anticipated by a sensitive government. Change is to be feared only if those responsible for the preservation of essential values falter in their task. In fact, change is welcomed in so far as it may strengthen the profession to meet the new challenges that confront our civilization. In times of change there is need for wisdom both in the external social order and within the profession. . . . A hold-fast in science is essential, but this represents only a part of the strength of Surgery. By maintaining the ancient bond with humanity itself through Charity—the desire to relieve suffering for its own sake—Surgery need not fear change if civilization itself survives."—Dr. Edward D Churchill, *Ann. Surg.* October, 1947, p. 381.

DEATH FROM RENAL ANOXIA AFTER MYANESIN ANÆSTHESIA

T. F. Hewer
M.D. Brist., F.R.C.P.
PROFESSOR OF PATHOLOGY

R. F. Woolmer
B.M. Oxfd, D.A
LECTURER IN ANÆSTHETICS

UNIVERSITY OF BRISTOL

Hæmoglobinuria following intravenous 'Myanesin' anæsthesia has lately been reported by Pugh and Enderby.[1] Their patients recovered, but attention was drawn to the possible occurrence of serious renal damage. Earlier in the year we had investigated a death following the administration of myanesin and were of the opinion that the drug might have been responsible; but, since we failed to determine the nature of the illness for which the patient was admitted to hospital, we did not feel justified in reporting the case. The demonstration of hæmoglobinuria attributable to myanesin prompts us to report it now.

A woman, aged 22, gave a history of rheumatic fever three years previously, when she was confined to bed for four months. She was said to suffer from asthma, having had an acute exacerbation two years ago, and was regarded as a semi-invalid, though there was no history of dyspnœa or distress on exertion The abdominal symptoms, ascribed to appendicitis, for which she was admitted had been present for seven months.

On admission she weighed 54 kg. The respiratory system was normal. There was a systolic murmur, but no cyanosis, clubbing of the fingers, congestion, or œdema. She could hold her breath only 15 sec., but she was very nervous on examination Her pulse-rate was 100 per min. The urine had a specific gravity of 1 024 and contained a trace of reducing substance but no albumin.

Operation (Feb. 18, 1947): appendicectomy and pelvic exploration. The appendix was not diseased. Anæsthesia: *8.30* A.M. *'Nembutal' gr.* $1^1/_2$ *(100 mg.)* by mouth, 9.30 A.M. 'Omnopon' gr. $^1/_6$ (11 mg.) and scopolamine gr. $^1/_{300}$ (0·22 mg.) intramuscularly; 10.30 A.M. thiopentone 250 mg. intravenously, followed by nitrous oxide and oxygen by the semi-closed method. Myanesin 13 ml. (1·3 g.) was given intravenously just after the incision was made. Relaxation being unsatisfactory, two further doses of 5 ml. and 10 ml. were given during the operation, making a total of 28 ml., equivalent to about 56 mg. of myanesin per kg. Pulmonary ventilation remained adequate, and the patient's colour was good throughout the operation, but considerable cardiovascular depression developed 10 min. after the third dose of myanesin, and the systolic blood-pressure fell to 70 mm. Hg. The patient was kept under observation in theatre for half an hour after the end of the operation, by which time the systolic pressure had risen to 95 mm. Hg.

Postoperative Course.—The patient vomited several times on the day of operation, and continued to vomit for next four days. On Feb. 22 hæmaturia was noted On the 23rd she had a series of epileptiform convulsions. Her blood-pressure was 140/90 mm. Hg and the blood-urea 290 mg. per 100 ml. Hæmaturia continued. A catheter specimen of urine taken in the evening had a specific gravity of 1·010 and an alkaline reaction; it contained numerous blood-cells and some granular casts. Pulmonary œdema developed during the day and became rapidly worse, and the patient was comatose by the evening. She died on the morning of Feb. 24.

Necropsy.—A well nourished well-built young woman 156 cm. in length, with some cyanosis, no œdema, and no cutaneous hæmorrhages. There were numerous minute hæmorrhages in the connective tissue between the muscles of the chest wall anteriorly. A few small recent hæmorrhages were also present in the mediastinum and alongside the epicardial veins on the posterior aspect of the heart. The appendicectomy wound was healing well, and the abdominal cavity was apparently healthy. The heart weighed 320 g. (slightly above average), but there was no apparent hypertrophy of any of the chambers, and the valves and coronary vessels appeared normal. There were no endocardial hæmorrhages. The aorta and large arteries, including the renal arteries, were entirely free from atheroma, and the venæ cavæ and large veins contained no thrombi but were considerably distended with blood. The renal veins appeared entirely healthy except for some distension. The air passages contained frothy fluid, and the lungs were extremely œdematous, with a few recent intra-alveolar hæmorrhages but no gross or histological evidence of infection. The liver and spleen were acutely congested. Examination of the shaft of the right femur revealed active red marrow throughout its whole length. Histologically this marrow showed active erythropoiesis and a rather large number of megakaryocytes. No abnormal cells were seen.

---

[1] Pugh, J. I., Enderby, G. E. H. *Lancet*, Sept. 13, p. 387.

The kidneys were much swollen, each weighing 170 g. The capsule of each stripped easily, leaving a perfectly smooth pale grey surface. On section the two kidneys were identical and had a striking appearance. The cortex was leaden grey, looking almost necrotic, and was evidently œdematous. There were no hæmorrhages in the cortex but some streaks of fresh hæmorrhage in outer zone of medulla, which was darker in colour. The renal pelves showed some petechial hæmorrhages but were not dilated or hyperæmic. The ureters appeared normal. The bladder was empty and showed some groups of recent hæmorrhages above and external to each ureteral orifice. There was no sign of infection of the bladder.

Histologically the kidneys showed much interstitial œdema but no cellular exudate. The glomerular capillaries contained little or no blood, but the afferent arterioles were uniformly dilated. There was no evidence of any arterial or arteriolar damage. All the convoluted tubules, the loops of Henle, and the collecting tubules were considerably dilated. The collecting tubules contained brownish granular material, much of which was present in the form of brownish ribbon-like casts. In places these casts were impacted in the tubules; at these sites there was some necrosis of the lining epithelium, and in one place a tubulovenous anastomosis was seen. The general appearance was that found in various conditions of the renal anoxia. There was no evidence of any antecedent renal lesion.

Histological examination of other organs showed no evidence of hypertensive vascular disease. The endocrine organs showed no change from normal.

DISCUSSION

This girl had never done any heavy work and was regarded as an invalid by her parents. Her rheumatic fever left no recognisable changes in the heart, and the clinical diagnosis of chronic appendicitis was disproved at operation. The only positive finding at necropsy that could have been present before the operation was considerable hyperplasia of red bone-marrow in the femur. No free iron was demonstrable in liver or spleen, and there was no history of jaundice; hence, with no hæmatological examination before death, the nature of the underlying blood disorder could not be determined.

Since the presence of hæmaturia was proved by microscopic examination of the urine during life, one cannot attribute the necropsy finding of brown debris in the renal tubules to intravascular hæmolysis. Hæmoglobinuria may or may not have been present. The important point is that the renal changes were those common to the numerous conditions attributed by Maegraith et al.[2] to renal anoxia. The presence of blood pigment blocking the tubules is to be considered a secondary factor, contributing in some degree to the renal embarrassment but not an essential part of the syndrome.

Intravascular hæmolysis, as in incompatible blood-transfusion, is one of the possible causes of peripheral vascular failure and so of renal anoxia; it is not necessarily accompanied by clinical jaundice. Now that hæmoglobinuria has been reported in association with myanesin anæsthesia, we feel justified in concluding that this anæsthetic was responsible for the fall of blood-pressure and thus for the renal changes. Since we were unable to determine the nature of the illness that led t patient to seek advice we cannot say to what extent may have contributed to the fatality.

SUMMARY

A postoperative death from uræmia is reported wi necropsy findings similar to those in incompatible bloo transfusion.

Reasons are advanced for ascribing the renal chang to the use of myanesin as an anæsthetic.

We are indebted to Mr. H. J. Croot, F.R.C.S., for permissi to use his clinical notes.

BILATERAL ZOSTER

REPORT OF A CASE

E. W. Prosser Thomas
M.D. Camb.

Bilateral herpes zoster is extremely rare. Epste and Jacobson in 1936 traced only 46 reported cases a they added 2 of their own. Subsequently, 1 case each h been reported by Rattner (1938), Ambler (1939), a Fourestier (1939).

In bilateral zoster the lesions may appear at the sa level on the two sides, but in most recorded cases th have been at different levels. The onset may be simu taneous on the two sides, or the second zoster may delayed for a day or longer. The bilateral disease see to have more severe prodromal symptoms than ordina zoster. For example, Rattner's patient had dizzine fever, vomiting, and severe headache for some da before the eruption appeared. In Ambler's case, in whic both sides of the neck were involved in the distributio of the 4th cervical nerves, there was a sudden onset wi malaise and fever (104°F), the eruption developin twenty-four hours later. Epstein and Jacobson, howeve doubt whether on the average the prodromata are an more acute than in ordinary zoster.

The dorsal nerves are said to be most often involve in bilateral zoster, and then the cervical nerves (includin the brachial plexus). There seems to be no particula tendency in bilateral disease for the eruption to be sever or for recovery to be delayed.

A married woman, aged 33, was admitted to hospita with lower abdominal pain of four days' duration. Th pain began in the umbilical area and later became generalise all over the abdomen. It was constant, with periodica exacerbations, which the patient likened to labour pains Menstruation had begun at about the same time and wa somewhat heavier than usual.

She had 2 children, who were well, and had had 4 miscarriage —1 at six weeks and 3 at seven months.

On admission she described the whole abdomen as feeling bruised. There was tenderness in both iliac fossæ and some guarding on the left side, with release pain. On vaginal examination a mobile anteverted uterus was felt, and there was tenderness and a suggestion of induration in the posterior fornix. The adnexa were not palpable. There was no psoas sign. Her temperature on admission was 99°F but was normal thereafter, as was her pulse-rate. No definite diagnosis was made, but salpingitis was suspected.

Within two days of admission the abdominal pain had subsided; but she complained of an ache in the small of the back. *A rash then appeared in this area* (about six days after the onset of the illness).

The eruption was a bilateral herpes zoster of mild but typical appearance. Groups of tiny pearly close-set vesicles on an erythematous base were distributed at about the same level on both sides in the upper sacral area and extended outwards over the hips and upper part of the buttocks. Some of the lesions on the left side were abortive, consisting only of patches of slightly raised erythema. The upper inguinal lymph-nodes on both sides were enlarged and tender. The lower lumbar spine was tender on pressure. Radiography of the lumbar spine showed no bone or joint disease.

The patient was treated with injections of 'Pitressin,' 0·5 ml., twice daily for three days. The herpes blisters dried

---

2. Maegraith, B. G., Harvard, R. E., Parsons, D. S. *Ibid*, 1945, ii, 293.

secondary infection, the lumbar neuralgia subsided, patient was discharged well about a week later.

I am indebted to Mr. Douglas MacLeod for permission publish this case.

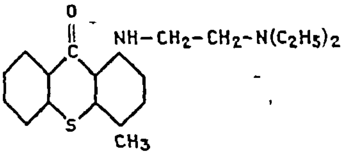
Preliminary Communication

THE EFFECT OF MIRACIL D ON HUMAN SCHISTOSOMIASIS

'MIRACIL D' is the hydrochloride of 1-methyl-4-beta-hyl-aminoethylaminothioxanthone.



t was synthesised by Mauss and was shown by uth and Gonnert to have considerable therapeutic vity for mice and monkeys infected with *Schistosoma soni.*[1] According to them, mice are cured—i.e., ms killed—with six doses of 60–120 mg. per kg., monkeys are cured with two doses of 5 mg. per kg. r the occupation of Germany this compound was ther studied in England. The pharmacology in small mals has been described by Wood,[2] and methods for mation in the body fluids have been described by ner et al.[3]

The pharmacology and toxicology in monkeys and n have been studied by two of us (F. H. and W. F. R.). compound is administered by mouth, since it is e toxic, or causes more local irritation, if injected venously or intramuscularly. Monkeys tolerate mg. per kg. four times a week. In man it is apparently rapidly absorbed from the alimentary canal, and hours after single doses of 0·2 g. the concentration the blood rises to about 1 mg. per litre. Over 90% miracil is degraded in the body, and only about 7% creted in the urine. There is little tendency for it accumulate in the body. The concentration in the ma is about twice that in the red blood-cells; the centration in the leucocytes is probably much higher. In animals deliberate long-continued overdosage may roduce degenerative changes in the liver and the renal tubules, but these are usually less than would be expected. In man the maximum tolerated dose for repeated administration is about 0·2–0·3 g. a day. In healthy British volunteers overdosage produced nausea and general prostration; insomnia and yellow discoloration of the skin and sclerotics also occurred. These symptoms came on after a latent period of about a day. Apparently they were not due to a direct action on the alimentary canal but rather to the formation of some degradation product of miracil.

CLINICAL TRIALS

By the kindness of the Southern Rhodesian Public Health Department it has been possible to carry out clinical trials at Salisbury.

Methods.—The patients were arranged in four groups. Group I, consisting of 3 African men, received 14 doses of 200 mg. Group II, consisting of 9 African schoolboys, received 12–13 doses of 100 mg. followed by 12–13 doses of 300 mg. Group III, consisting of 13 African school-children, received 18–22 doses of 200 mg. Group IV consisted of 17 Eurafrican children; 6 larger boys received 19 doses of 200 mg., and 11 smaller children received 6 doses of 100 mg. and 13 doses of 200 mg. The compound was administered as uncoated tablets, once daily after the midday meal, for six days a week; preliminary doses of 50 mg. were given to each patient, to exclude idiosyncrasy, before the above courses were begun.

At the start the patients were passing viable ova of *S. hæmatobium* or of *S. mansoni*; but, apart from hæmaturia in a few of them, they were not suffering from any obvious disability as the result of their infection, and they seemed all vigorous healthy subjects. All but 3 of the patients infected with *S. mansoni* were also infected with *S. hæmatobium*. The patients were examined at intervals of four- to seven days during treatment, and then at fortnightly intervals for two months after the last dose.

Results.—Immediately after the cessation of treatment 6 of 41 patients with *S. hæmatobium* infection, and 2 of 12 with *S. mansoni* infection, were no longer passing eggs. At the end of four weeks 11 of 41 with *S. hæmatobium* infection, and 4 of 12 with *S. mansoni* infection, were no longer passing eggs. At the end of eight weeks 9 of 40 with *S. hæmatobium* infection, and 2 of 11 with *S. mansoni* infection, were no longer passing eggs. One patient with a double infection was not examined.

The criterion of a case being negative was the absence of eggs on microscopical examination. Thus 22% of patients with *S. hæmatobium* infection and 18% of patients with *S. mansoni* infection became negative eight weeks after the treatment ceased.

DISCUSSION

Most of the patients who ceased passing eggs had been only lightly infected; so too much significance should not be attached to them. In some the cessation of egg-passage during the three-month period of observation may have been spontaneous. In some the passage of eggs ceased during the period of observation but eggs were found again at later examinations. It is concluded that in this clinical trial the therapeutic action of miracil D, if any, was slight.

Possibly the drug was responsible for cure in some of the cases, but this cannot be proved. Certainly the great majority of the patients continued to pass living ova after these courses of treatment, which are considered to be about the maximum tolerated. Even on the most favourable interpretation of the results the therapeutic effect of miracil D was greatly inferior to that usually exerted by antimony preparations, and it was not great enough to be of any practical value.

These courses of miracil were well tolerated by most of the patients. One man in group I had intense nausea, anorexia, and weakness for several days at the end of the course; these symptoms may have been due to miracil. Two others had slight or moderate nausea. Various boys reported slight abdominal pains when questioned, but these are common among African children and are probably not significant. There were no significant alterations in the hæmoglobin or white-cell counts during and after treatment. One European (not included in the results recorded above) became distinctly yellow in the conjunctivæ and skin while taking miracil, but he had no other symptoms; eight weeks after treatment he still continued to pass occasional viable eggs of *S. hæmatobium*.

Details of these investigations will be published in the *British Journal of Pharmacology and Chemotherapy*.

SUMMARY

Miracil D is a new compound which has been reported to be therapeutically active for infections of mice and

[3] Latner, A. L., Coxon, R. V., King, E. J. *Trans. R. Soc. trop. Med. Hyg.* 1947, 41, 133.

monkeys with *Schistosoma mansoni*. It was given in maximum tolerated dosage for three weeks to 42 African and Eurafrican patients infected with *S. hæmatobium* (38 cases) and/or *S. mansoni* (11 cases). The results were disappointing. Two months after the end of treatment, 86% of the patients were still passing living ova.

In this series of cases the therapeutic effect of miracil was not great enough to be of real clinical value.

Grateful acknowledgments are due to the Medical Director, Southern Rhodesia, for clinical facilities and encouragement; to all the workers mentioned above for information about their results and for material; and to the volunteers who made possible the study of the pharmacology of miracil in man.

Reviews of Books

British Surgical Practice

Vol. I. Editors: Sir E. Rock Carling, F.R.C.S., F.R.C.P., consulting surgeon, Westminster Hospital; J. Paterson Ross, M.S., F.R.C.S., surgeon and director of surgical clinical unit, St. Bartholomew's Hospital, professor of surgery in the University of London. London: Butterworth. 1947. Pp. 536. 60*s*.

The publication in this country of a comprehensive new textbook of surgery is a notable event. The last big book of this kind published in Great Britain was Maingot's *Post-graduate Surgery*, but the rapid advances of the past ten years have dated it, and have made its great predecessor, Choyce, seem positively old-fashioned. The time was ripe for the appearance of *British Surgical Practice*, the first of the eight volumes of which has now appeared, and Sir Ernest Rock Carling and Prof. Paterson Ross, as general editors, have collected round them a distinguished team of contributors.

The work is intended as a guide for surgeons who have no easy access to libraries, being written neither for the expert in any particular specialty nor for the undergraduate. Operative technique is described in detail, but operations which are no longer regularly employed have been excluded. The old regional grouping has been discarded, and the sections substituted are instead arranged alphabetically. Thus, vol. I contains 45 sections, starting with abdominal emergencies and ending with the autonomic nervous system. Almost every section is by a different author, each an accepted authority in his own sphere. The book is beautifully printed, illustrated, and bound, and each volume has an index. A comprehensive index is to be published, at the end, as a separate volume to cover and cross-reference the other volumes.

The sectional arrangement is thought to make for easy reference; but how it will work out can scarcely be judged until the book has been used on the day-to-day problems of practice. The editors must have had some trouble to decide the headings and scope of each section, and to avoid undue dissection and separation of subjects: one section, for example, is entitled "Anus, artificial (management)" and one wonders why this matter is not dealt with where the operation of colostomy is described; and the operation of tracheotomy, details of which might be required in a hurry, is described under "Air Passages." The comprehensive index no doubt will overcome such difficulties as these, but it is evident that the sectional alphabetical arrangement brings its own problems.

In these days of rapid progress and rapid change of fashion in surgical thought, the bound volume is at a disadvantage: parts of it are out of date almost as soon as printed. *British Surgical Practice* is to be kept up to date by the publication of an annual supplement—in some ways a less satisfactory solution than the production of a new edition, but necessary when a new editi costs £25 a set.

There are many valuable articles in this first v and little to criticise. One or two of the sections mi have been telescoped: acidosis scarcely merits 7 and could have been included in a later section dehydration and chloride deficiency following. The section on the abdominal wall is concerned with the surgical anatomy of incisions and their repai good as it is, it should surely also say something abo the diseases affecting this region. Achlorhydria cann easily be discussed apart from the stomach, and t section on adiposity would have been more useful some specimen menus had been included. These a small things to set against such articles as those abscess (Prof. Geoffrey Hadfield), amputations (M George Perkins), acute appendicitis (Mr. Wardlewor Nuttall), and arthritis (Mr. Norman Capener). Those w possess the first volume will be eager to see its successo

Textbook of Pathology

(6th ed.) E. T. Bell, M.D., professor of patholo University of Minnesota. London: H Kimpton. 19 Pp. 910. 50*s*.

Two years after the last, the sixth edition of Bel well-known textbook is presented from the departme of pathology in the University of Minnesota, w Professors Clawson and McCartney contributing before. The text is concise rather than discursive, a the student must needs remember most of what he rea The large majority of the key references at the e of each section are, understandably, to the Americ literature. The book has been well revised, with or slight increase in size, but although the blood-level f severe ethyl-alcohol intoxication has been reduced fro 0·4 % to 0·3 % in this new edition the amount "consider sufficient to cause death" remains at the high value 1% (0·5 % according to Glaister and Jetter). In Pr fessor Bell's experience "the chronic drunkard has large fatty liver, seldom with cirrhotic changes"— contrast to the findings of many other American write The book is good and comprehensive; in a futu edition the remaining drawings could well be replac by photomicrographs.

Curare

Its History, Nature, and Clinical Use. A. R. McIntyr M.D., PH.D., professor of physiology and pharmacolog University of Nebraska. London: Cambridge Univers Press. 1947. Pp. 240. 27*s*. 6*d*.

This book surveys past and present knowledge of t use of curare in all its aspects, and includes a compr hensive bibliography. Although investigated over sever centuries curare has only recently been used in clinic medicine for the control of tetanus and other convulsi states; and now that a standardised preparation available the clinical applications have multiplie rapidly. It promises well as an adjuvant in anæsthesi inducing muscular relaxation in the lightly anæsthetise patient. The glowing reports from experts may, howeve lead the inexperienced into using it in a thoughtless o too light-hearted manner. Bronchospasm is among th possible dangers, and abolition of respiration among it peripheral actions. More important is the fact that i also has a central action which may be induced by a heav initial dose or by prolonged curarisation.

A Short Textbook of Surgery (4th ed London: J & A Churchill. 1947. Pp. 680. 30*s*.)—This edition, though shorte by a few pages than its predecessor, includes entirely ne sections on arterial injuries, dysphagia, and rehabilitation Many chapters have been completely rewritten, all have bee brought up to date, and 26 new illustrations have been added It is inevitable that where space is rigidly economised man controversial subjects must be treated somewhat scantily but on the whole Prof. C. F. W. Illingworth has preserved skilful balance, and has avoided dogma. Some of the illus trations should be either improved or dispensed with—e.g. the one showing investigation of an inguinal hernia by invaginating the scrotum, and that depicting injection of pile into the centre of its substance. The book as a whole however, is sound and useful.

THE MALE CLIMACTERIC ♂

Climacteric symptoms occur in men as in women, the result of decreased function of the sex glands.

The symptoms are as effectively relieved by Androgenic as are those of women by Oestrogenic therapy.

Carcinoma of the prostate is the chief contra-indication.

The use of sex hormones to increase sexual potency is often disappointing and should be avoided.

Testosterone Organon (Neo-Hombreol) is available in base form in 15 mg. suppositories; as a propionate in 5, 10 and 25 mg. ampoules and by mouth as Methyl Testosterone (Neo-Hombreol (M)) in 5 mg. mucosets. References and abstracts on request.

TESTOSTERONE

by

ORGANON LABORATORIES LTD.

Engaged solely in the production and distribution of natural and synthetic hormones, vitamins and related therapeutic substances

After Debilitating Illness

Allenburys Beef Juice is particularly suitable for administration in convalescence after severe and debilitating illnesses. It is not merely a stimulant but contains, in palatable and concentrated form, the nutritious and stimulant constituents of fresh, raw, beef juice, including albumen which is conserved by the process of manufacture *in vacuo* at a low temperature. Allenburys Beef Juice provides an easily administered, highly beneficial supplement to the diet.

In bottles at 3/- and 5/8 each.

The Issue

THE Negotiating Committee's long-awaited statement is brilliant but a little disappointing. Instead of discussing how best the National Health Service Act can be made to work, they seem to have spent the past nine months in elaborating the case for its amendment. Nevertheless the documents released this week broadly fulfil the prediction made last spring that the controversy would narrow down to a single major issue—whether doctors joining the service should continue to own the goodwill of their practices. The majority of the committee are convinced that they should do so: "the ownership of goodwill," they aver, "is regarded by the medical profession as fundamental to its freedom." They have therefore endeavoured to deflect the Minister from his purpose by proving that abolition of the sale and purchase of practices is unnecessary and that (as the Act now stands) it might cause grave hardship and grave injustice.

First, then, is abolition necessary? The ostensible reason for insisting on it immediately is that in the National Health Service the Minister is expected to ensure that medical resources are distributed throughout the country in accordance with needs: it will be impossible to do this so long as doctors are able to buy practices wherever these are vacant, for in so doing they tend to concentrate in the pleasanter or more lucrative areas. This argument the Negotiating Committee counters by saying that when the same medical payment is to be had in respect of every person in the country the doctors will tend to concentrate on previously under-doctored areas where they are likely to collect more capitation fees; and so far as necessary they can be attracted to specially unpleasant or sparsely populated districts by the offer of additional payments. The Minister does not dispute this favourable tendency, but he thinks "it cannot be assumed," especially when doctors are scarce, that it will result in their distribution according to population. In so far as the committee is right, and defects in distribution will automatically be corrected in a service providing payment for every citizen, the need for interfering with the present method of filling practices by purchase is diminished. And as distribution improves there will be correspondingly less need to invoke those powers of "negative direction" to which so much exaggerated objection has been taken. The Minister is justified in claiming that power to close a vacant practice in an over-doctored area is necessary if he is to be sure of carrying out his duties; and, as he remarks, it is unusual to insist on receiving publicly remunerated work—as a school-teacher for instance—wherever one chooses to do it. But we should all prefer to see such powers kept in the background, and the creation of a fund of about £400 000 a year for positively attracting doctors to unpopular areas should do much to that end.

On the effects of the Act, the committee put up an impressive case in favour of their opinion that "abolition of the custom of buying and selling practices creates more problems than it solves." Certainly many doctors who were otherwise prepared to surrender the goodwill of their practices—in return for compensation at an average figure of over £3600—have been alarmed at the complex penal clauses by which the lawyers have tried to prevent circumvention of the Act. Their fears will be increased by the committee's picture of chaos created by ambiguities of wording and by uncertainty whether partnership agreements will stand after the appointed day; and particularly by the examples of difficulties that may arise over the apportionment of compensation and interest, the sale of houses, and the appointment of assistants. By all this recital, however, the Ministry remains apparently unperturbed: it holds that in general the problems can be solved by appropriate regulations, and that the exceptional case can be met by partners varying their agreements to fit the new circumstances. Nobody will deny that the difficulties exist, but "hard cases make bad law." Perhaps too, the committee would have found the difficulties less formidable if they had shared the widespread opinion that discontinuance of the sale and purchase of practices is in itself a good thing, worth pursuing at the cost of temporary inconvenience. To the Government, to a large proportion of the public, and to a great many doctors the sale of practices is an anachronism comparable to the sale of commissions in the Army; more, it is a manifestation of the commercialism which has infiltrated medicine with deplorable consequences and which we are anxious to reduce. To a majority of the committee, however, it remains a cause worth fighting for.

Nor is their argument negligible by any means. First, the desire to increase the capital value of a practice is an incentive to good and keen work. (But so, to some extent, is the desire to increase income and pension.) Secondly, ownership of goodwill provides a basis for coöperation between practitioners. (But, as the Minister says, there seems to be no reason why the buying and selling of shares should be regarded as the essence of a medical partnership.) Thirdly, and more important, so long as a man has a practice which is his own, in the sense that he can sell it, he has a feeling of professional independence. He is like the employee with private means who can snap his fingers at his employer: he is a sovereign State with a medical service of his own. True, the goodwill of his practice does not really give him much more security than an equivalent balance at the bank or in the Treasury, but in either case he has an advantage over the young doctor entering the National

Health Service with neither one nor other. If the practitioners of the future are not to enjoy the private security of a saleable practice they must be given a high degree of public security—the certainty of fair treatment with no possibility of being victimised for holding heterodox or unwelcome opinions. The penalty of removal from the service will become increasingly severe as the possibilities of private practice contract, and it is a sound instinct which has led the profession to ask repeatedly that the final decision on removal shall be made in a law-court and not at the Ministry. The Minister has not got over this difficulty by his offer to consult another advisory body; but conceivably a way out is indicated by his remark that an aggrieved doctor can go to the courts on the grounds of unlawful action. If after failing to convince the medical services subcommittee (set up by the local medical committee and the local executive council), the tribunal, and the Minister with his advisory committee, a practitioner is still able, under the Crown Proceedings Act, to sue the Minister for wrongful dismissal, may we not be satisfied? The answer is yes—but only if members of the service remain perpetually alert in the cause of professional freedom and ready to defend it at all levels. As with so much in this service, the remedy here lies with ourselves. Whatever the Negotiating Committee may say, the proposed organisation offers the profession great opportunities of influence, and these opportunities will further increase if they are well used. Whether the service is good or bad depends chiefly on what we choose to make it. The spirit is far more than the letter

This rôle of doctors in shaping the service is not something potential which we have merely imagined: it is an extension of something already begun. On regional hospital boards and local executive councils many medical men and women have begun to play their part, and they have discovered that decentralisation of responsibility under this Act is a reality —that the tasks offered them are anything but trivial In the vast reorganisation of hospitals which is now in progress, the medical profession is already deeply involved. All of which takes us back to a brief paragraph at the beginning of the Negotiating Committee's statement which admits that certain parts of the Government's scheme are commended or accepted by the profession, including the proposed planning and development of hospital services on regional lines, the general structure of local executive councils, and the principle that the service should be available to the whole community. This paragraph is in fact more significant than any that succeed it; for it virtually buries the possibility that the profession will in the end refuse to take part in the National Health Service—though concessions may be necessary before it commits itself. The only big question which remains to be decided is whether general practitioners are prepared, on entering the service, to surrender the goodwill of their practice in the manner laid down under the Act The scale of compensation long ago arranged, and the range of remuneration now offered, are reasonable without being lavish; and, though the new proposals would probably increase the income of a large number of practitioners and would make things much easier for new entrants to practice, they are not so dazzling as to blind anyone to a vital principle. Is the ownership of goodwill really a vital principle? Is the Negotiating Committee right in thinking that it is "in the best interests of the public and the profession" that general practitioners should retain it? These are questions on which we shall all have to make up our minds. But even if the profession decides that the Minister's proposals about goodwill are unsound or intolerably vexatious, this need not necessarily mean that the general-practitioner service cannot be started next July. Rather than face a postponement which would be highly inconvenient to the profession as well as the Government it would be possible to bring the Act into operation without applying those sections which alter the present methods of filling vacant practices. In this way the difficulties now arising through the shortage of time could be overcome, and the legal situation could be more fully explored. Preferable as it would be to a paralysing dispute, this expedient might nevertheless (as the committee said of abolition) create more problems than it would solve—especially for the many younger men who have lately taken on large commitments. We sincerely trust therefore that it will not have to be considered.

Mr. ANEURIN BEVAN is a controversial figure who attracts accusations. He is accused of deceiving the Negotiating Committee in that he was never really prepared to submit an amending Bill to Parliament before the Act was tried He is accused of using a politician's guile to divide the profession, because he seems to listen rather more readily to the spokesmen of specialists than to the spokesmen of general practitioners He is accused of a failure in political wisdom because, when he feels sure of his position, he does not allow his opponents to capture those minor trophies without which they cannot comfortably reappear at home An outstanding Parliamentarian, the Minister may in fact have faults as a negotiator. Two things, however, must be said in his favour: he has already been proved right in his bold solution of the almost insoluble problem of the hospitals; and he has also—on paper at least—been consistently conciliatory and reasonable in his pronouncements of the past year. In one sentence only of this week's memorandum does he react to the tone used by the Negotiating Committee—when he says that hardly any major step to better social services has provoked more misstatements or misunderstandings than his Act Not everyone would agree that this is so, but none can deny that the less attractive features of the National Health Service have had disproportionate emphasis The Negotiating Committee has of course good reason to claim that "the medical profession itself has provided the main impetus towards the establishment of a comprehensive health service"; but the cautious attitude of the profession has been such that in the eyes of the public it has seemed to oppose all schemes for such a service, from the Coalition's white-paper onwards Certainly among doctors the result of this caution has been a widespread feeling of dissociation from a reform which, though it goes farther and faster, embodies what the profession has long demanded; and errors on both sides have unhappily created the mentality of the conscript in men who ought to be volunteers. Fortunately it is not too late for a change of attitude. The Minister's new appeal for genuine and willing cooperation is one that must not go unanswered, for the opportunities of this early stage of the service are opportunities that will never recur.

Pandemic Diphtheria

THE extent to which diphtheria became pandemic during the late war is not generally realised. Stowman,[1] consultant epidemiologist to the World Health Organisation Interim Commission (WHOIC), estimates that in Europe, excluding the Soviet Union, Poland, and the Balkans, for which data are either absent or inadequate, there were soon after the war began not less than 600,000 cases a year, and that the total deaths for the war and immediate post-war years probably exceeded 150,000 The pandemic is now receding, but in 1946 the cases reported in this area numbered 336,000, which is still two-thirds of the peak incidence

When the war broke out Germany differed from the neighbouring countries in having a diphtheria incidence which had been steadily rising for nearly fifteen years Inoculation against diphtheria was not compulsory for German children, nor was it being practised in Germany on a big enough scale to offset the increased risks of infection arising from the extensive development of community life, particularly among young people The main focus of epidemic diphtheria in Germany, then as now, was the North Sea area—i e. Hanover, Schleswig-Holstein, and Berlin. It was probably from this focus that a wave of high diphtheria incidence spread when the German armies broke through on all sides in the spring of 1940 Sweden and Denmark managed to resist this epidemic wave to some extent, but Norway and Finland suffered severely, as did the Netherlands, where an epidemic promptly appeared on the heels of the invaders and with them reached Belgium and France, also spilling over slightly into neutral Switzerland. In several ways our own position during these momentous events was exceptional. In the first place the United Kingdom was not at the outbreak of war an area of low incidence, the median of cases reported annually from 1928 to 1938 being about 75,000 Then communications with the Continent were almost completely interrupted in four of the war years, and the efforts of an energetic public-health service pursuing a well-organised campaign of child immunisation apparently built up a substantial resistance to diphtheria by the time communications were reopened in 1944 England, Scotland, Wales, and Northern Ireland went through the war without any epidemic of diphtheria, and by 1946 the annual incidence of confirmed cases had fallen to 16,000, less than a quarter of the 1928–38 median. Eire, where no extensive immunisation of the child population was carried out during the early war years, had a very different experience, with a peak incidence of diphtheria in 1944 three or four times the incidence in 1941 Mediterranean Europe, and North and South America, escaped the pandemic altogether. The resistance of Mediterranean Europe and the Latin American countries, unlike that of the United States and Canada, cannot be claimed as a result of artificial immunisation and must be ascribed to the unknown factors which have for a long time made these areas unfavourable to the spread of diphtheria. In the Pacific area, where Japan with a rising pre-war incidence seems to have played a part resembling that of Germany in Europe, there was an epidemic in the invaded Philippines and a substantially increased prevalence, reaching a peak in May–July, 1946, in New Zealand.

Denmark was almost the only affected country in which the epidemic wave was carefully studied. Mortensen[2] has shown that in Copenhagen between 1939 and 1945 there was a striking change in the age-distribution of diphtheria cases; of the recent admissions to hospital only a third were children as against three-quarters in pre-war years. Immunisation in Denmark did not begin until 1941, but in Copenhagen the campaign was very successful and as many as 95% of the children were inoculated. Nevertheless in 1944 that city had 1754 cases of diphtheria, compared with only 41 in 1942 Typing studies showed that the outbreak in 1944 was caused chiefly by gravis strains of *C diphtheriæ*, which appeared to have a greater capacity than mitis strains for breaking down the defence conferred by inoculation and were associated with a high case-mortality rate in the uninoculated.

Large-scale international studies of global epidemiology require reliable national data collected in a uniform manner. In Sweden, where diphtheria carriers as well as cases are notified, the reporting of about equal numbers in the two categories suggests that an attempt should be made to reach some international agreement on the definition of a diphtheria case. It is already evident that information on the number of cases and deaths will need to be supplemented by data regarding prevailing types of infection, the age-incidence, and the state of inoculation of the population at risk, before the maximum possible control of diphtheria can be achieved

Synthesis of Vitamin A

NEARLY twenty years ago von Euler et al.[3] reported that carotene possesses the physiological activity of vitamin A; and soon afterwards Moore[4] showed that animals are capable of converting this yellow plant pigment into the colourless vitamin The chemical investigations of Karrer et al.[5] confirmed that vitamin A is a carotenoid derivative, and indicated that it is an alcohol with a molecular weight about half that of the parent hydrocarbon Karrer's structural formula, consisting of a terpene-like β-ionone nucleus joined to a polyene side-chain with a terminal hydroxyl group, has been accepted by all subsequent investigators.

Despite this relatively simple structure, the vitamin has proved difficult to synthesise, largely because of its sensitivity to oxidation and its general chemical instability. Both Karrer and Heilbron, with their respective schools, have done valuable exploratory work. The first claim to have synthesised the vitamin was made in 1937 by Kuhn and Morris[6]; but their product was admittedly impure, and the synthesis appears to have been neither exploited by themselves nor confirmed by others. Later the synthesis of a derivative of vitamin A, in the form of the corresponding methyl ether, was reported by Kipping and Wild,[7] but again confirmation was lacking. Isler et al.[8] have also claimed the synthesis of the same ether by a different route, and have found it to have biological activity. Milas[9] has apparently synthesised several biologically active ethers and esters, and also the vitamin itself in impure form. Since all his products were somewhat inferior to the natural vitamin in their biological activity he concluded that they contained a high proportion of *cis* isomers. These modifications differ from the natural *trans* isomer in having their polyene side-chain bent back upon itself instead of straight, presumably with a considerable reduction in biological activity.

Another claim to have synthesised vitamin A, this time by a novel and interesting procedure, has recently been made by the young Dutch chemists, van Dorp and Arens.[10] With β-ionone as a starting-point they obtained by a well-established procedure the C_{18} ketone corresponding to vitamin A. This compound was then treated with ethoxyethylene magnesium bromide to add four more carbon atoms, and the resulting C_{22} ketone was partially hydrogenated, and rearranged and hydrolysed by treatment with hydrochloric acid to form vitamin-A aldehyde. This product was spectroscopically identified with vitamin-A aldehyde as obtained by oxidation of the natural vitamin; and it was reduced by treatment with aluminium isopropoxide to yield vitamin A itself, though not yet in a pure state. Whether the method is suitable for exploitation on a large scale remains to be decided: there should at least be no shortage of the starting material, β-ionone, which can be readily extracted or prepared from vegetable sources. Even on a laboratory scale, however, a successful and indisputable synthesis of vitamin A in pure and stable form would fulfil an ambition long cherished by organic chemists, and confirmation of the new work will therefore be awaited eagerly. Meanwhile the claim made by the Dutch workers[11] to have synthesised the acid corresponding to vitamin A may perhaps be still more interesting to those studying the vitamin from a biological angle. This acid appears to have a potency equal to that of vitamin A when it is administered orally as the sodium salt.[12] It is said to differ in two ways from all other substances having vitamin-A activity: (1) even large doses do not give rise to storage of vitamin A in the liver[13]; and (2) subcutaneous injections of the sodium salt are only slightly inferior in biological activity to the same doses given orally. These two findings, if confirmed, will have bearings both on our knowledge of vitamin-A metabolism and on vitamin-A therapy in diseases where intestinal absorption is impaired.

Annotations

TO BE CONTINUED

For fifty years the voluntary hospitals of Londo have been largely sustained by King Edward's Hospit Fund, which, particularly in time of crisis, has afforde indispensable support. Now that the maintenance cos is no longer to be borne by private purses, the fun is preparing for a different, though no less valuable allocation of its resources. At a council meeting hel at the House of Lords on Dec. 8 H.R.H. the Duke o Gloucester pointed out that money given to particula hospitals will enable hospital committees to do man things impossible within the limits of a strict budget "and we are confident that the flow of voluntary gift will continue." The fund, he said, was concerned wit much that was going to influence the quality of th future service: the training schemes for administrato caterers, and domestic supervisors were being developed and that for administrators had already proved a grea success. Moreover, the fund's work for the recruitment of nurses continued to augment the efforts of th individual hospitals; and the Emergency Bed Servic was still expanding.

Sir Wilson Jameson, as chief medical officer of th Ministry of Health, remarked that the Ministry and th various boards and committees charged with organisin the National Health Service will have their hands ful "and it is here that the importance lies of having a organisation independent of the Government but workin happily with them." With its progressive and enlightene policy in recent years, the fund had led the way in such matters as the Emergency Bed Service, nursing recruitment, training bursaries, and convalescent homes, and these were pointers to future possibilities.

EARLY RECOGNITION OF RHEUMATIC HEART DISEASE

We are still curiously ignorant concerning the incidence of rheumatic heart disease and its early signs. The mass examination methods of war-time provided a unique opportunity to stop these gaps in our knowledge, and Parkinson and Hartley[1] have analysed their findings in 2500 men referred by medical boards in 1940–45 because of suspected heart disease. Of these men, 806 were found to have heart disease, and in 609 of them (i.e., 76%) rheumatic heart disease was diagnosed. This ratio of rheumatic to non-rheumatic disease closely follows the American figure, for Wilburne and Coccolini[2] found that heart disease accounted for 6% of the rejections of recruits on mental or physical grounds, and that 63% of the cases were rheumatic. In the hospital population as a whole Bruce Perry[3] found that 38% of heart cases were rheumatic.

In the recognition of rheumatic heart disease Parkinson and Hartley place greatest reliance on radioscopy and a careful examination, including auscultation with the patient erect (or sitting), lying on his back, and lying on his left side after exercise. The history is also important, but it is unreliable because it can easily be falsified. Routine electrocardiography was soon discarded because its value was found to be limited except in specially difficult cases or those with arrhythmia. Of the entire group, 264 (i.e., 32% of all rheumatic cases) had mitral valvular disease, 184 of these having mitral stenosis and 12 mitral incompetence, while in 68 the diagnosis was "mitral valvular disease probable." Of the 184 recruits in whom mitral stenosis was diagnosed, 104 had a presystolic murmur, 13 a mitral diastolic murmur, 5 a loud apical first sound, 2 no auscultatory abnormality

1. Parkinson, J., Hartley, R. *Brit. Heart J.* 1946, 8, 212.
2. Wilburne, M., Coccolini, L. M. *Amer. J. med. Sci.* 1944, 207, 201.
3. Perry, C. B. *Brit. med. J.* 1931, i, 278.

radiological evidence of mitral stenosis, and 60 only systolic murmur. This last group is the most important from the point of view of early recognition, and two questions immediately arise—(1) is the murmur functional ("incidental," as Parkinson calls it) or indicative of valvular disease; and (2) if the latter, does it denote mitral incompetence or stenosis? The series contained three groups of cases with an apical systolic murmur—the 60 thought to have mitral stenosis, the 12 diagnosed as mitral incompetence, and 45 of the 68 mitral-disease-probables. How were these differentiated? The two main criteria of stenosis were the loudness and length of the murmur and the typical cardiac outline on radiography. The 12 cases diagnosed as mitral incompetence had apical systolic murmurs; 6 had a history of previous rheumatic infection; and 5 showed general enlargement of the left ventricle. Of the 68 recruits in the "probable" group there was a previous history of rheumatic fever or chorea in 45; a history of dyspnœa in 14 and of hæmoptysis in 1; an apical systolic murmur in 45; an accentuated apical first sound in 24; a doubtful systolic murmur in 9; some radiological evidence of enlargement in 38; and right axis deviation in 4. In this group the history, symptoms, and signs together strongly favoured the diagnosis, but they were not conclusive, and in half of them the X-ray note was "doubtful enlargement of the left auricle."

Aortic incompetence was found in 202 of the 2500 men, and all of these had a typical diastolic murmur. That so many cases were found is a striking commentary on the ease with which the diagnosis may be missed in the early stages. The murmur may be so soft as to be missed unless it is specifically and correctly listened for—i.e., to the left of the sternum in the 3rd or 4th interspace, with the patient erect or sitting up and leaning forwards while holding his breath. With these precautions it should not be missed except by those unfortunate auscultators whose hearing is defective in the higher ranges. In the early stages, however, the murmur may not be present all the time, so repeated auscultation may be necessary. Aortic stenosis, of which there were 14 examples in the series, provides no great difficulty. This diagnosis may be made in the absence of a thrill, but a thrill is usually present, though it may be missed if the hand is pressed too hard over the aortic area; light but firm pressure is the secret of successful palpation.

In his Lumleian lectures some years ago Parkinson[4] said: "By radiocardiology we shall reach a more vital anatomy and physiology, and—earlier in disease—a dynamic pathology of the living heart." His latest investigation confirmed the vital importance of radiology in the diagnosis of heart disease. A full clinical examination is a sine qua non but will not reveal every case. Clinical examination and radiology together make it possible to recognise the vast majority, though there are still a few cases (60 in this series) in which doubt must remain; in these phonocardiography may well provide the diagnosis. It is abundantly clear from this investigation (though the fact has not yet penetrated to the textbooks) that a presystolic murmur is not the earliest sign of mitral valvular disease. From what we know of the natural history of the disease this is not altogether surprising. As the mitral cusps become gradually involved in the rheumatic inflammatory process it is logical to assume that, before becoming adherent to each other and producing stenosis, they should pass through a stage where they are merely slightly retracted and therefore incompetent. This stage is not commonly recognised because there are no symptoms and therefore the patient is not examined unless he wants to join the Forces or insure his life.

TETRAETHYL AMMONIUM IN PEPTIC ULCER

THE major feature of modern therapeutics is the constant stream of new drugs, but a minor one is the discovery of new uses for familiar compounds. Thus the tetraethyl ammonium compounds were investigated pharmacologically many years ago, but are now being reinvestigated both in this country and in the United States. Principal interest has hitherto centred on their effect on blood-pressure, which, though transient, may be useful in the diagnosis and even the treatment of hyperpiesia and peripheral vascular disease. From animal experiments the compounds appear to act by blocking autonomic ganglia, but there is some doubt whether they exert an exactly similar action in man. Little et al.[1] have now studied their effects on gastric ulceration artificially produced in rats. This is not the occasion to discuss how far peptic ulcers in animals resemble those in man. The important thing is that the course of peptic ulcers produced by pyloric ligation in rats appears to be significantly modified by the administration of 1 mg. doses of tetraethyl ammonium chloride intramuscularly before operation and hourly afterwards. The treatment was continued until the death of the controls from perforation or of the treated by sacrifice, and there was a striking difference in number and size between the ulcers in the control and in the treated group. Further, whereas the ulcers in the controls mostly perforated, the treated rats showed only minor lesions and 3 had none at all. These results have been thought sufficiently promising to justify a tentative clinical test, and Little and his co-workers, encouraged by the results in two cases, are staging more extended trials.

BOECK'S VERY FIRST SARCOID

John H. Stokes and his associates[2] have defined the sarcoid group of disorders as cutaneous affections ranging from erythema to tumour formation, characterised by a benign course and absence of ulceration. They find the lesions distinctive in the formation of proliferative tubercles composed of endothelioid cells and sparse numbers of Langerhans giant cells, usually with a slight lymphocytic reaction; caseation does not take place. Tubercle bacilli or other organisms cannot normally be demonstrated in the lesions. In their classification of the group they include four forms: Boeck's benign miliary sarcoid, lupus pernio of Besnier, angiolupoid of Brocq and Pautrier, and the subcutaneous sarcoid of Darier-Roussy.

Prof. Cæsar Boeck's patient in 1896, aged 36, and in 1940, aged 80. (Reproduced from Prof. N. Danbolt's paper.)

Cæsar Boeck's first case of "multiple benign sarcoid of the skin" has been re-examined by Danbolt,[3] who says that this patient's record was published by Boeck work. The first claim to have synthesised the vitamin was made in 1937 by KUHN and MORRIS [6]; but their product was admittedly impure, and the synthesis appears to have been neither exploited by themselves nor confirmed by others. Later the synthesis of a derivative of vitamin A, in the form of the corresponding methyl ether, was reported by KIPPING and WILD,[7] but again confirmation was lacking. ISLER et al.[8] have also claimed the synthesis of the same ether by a different route, and have found it to have biological activity. MILAS [9] has apparently synthesised several biologically active ethers and esters, and also the vitamin itself in impure form. Since all his products were somewhat inferior to the natural vitamin in their biological activity he concluded that they contained a high proportion of *cis* isomers. These modifications differ from the natural *trans* isomer in having their polyene side-chain bent back upon itself instead of straight, presumably with a considerable reduction in biological activity.

Another claim to have synthesised vitamin A, this time by a novel and interesting procedure, has recently been made by the young Dutch chemists, VAN DORP and ARENS.[10] With β-ionone as a starting-point they obtained by a well-established procedure the C_{18} ketone corresponding to vitamin A. This compound was then treated with ethoxyethylene magnesium bromide to add four more carbon atoms, and the resulting C_{22} ketone was partially hydrogenated, and rearranged and hydrolysed by treatment with hydrochloric acid to form vitamin-A aldehyde. This product was spectroscopically identified with vitamin-A aldehyde as obtained by oxidation of the natural vitamin; and it was reduced by treatment with aluminium isopropoxide to yield vitamin A itself, though not yet in a pure state. Whether the method is suitable for exploitation on a large scale remains to be decided: there should at least be no shortage of the starting material, β-ionone, which can be readily extracted or prepared from vegetable sources. Even on a laboratory scale, however, a successful and indisputable synthesis of vitamin A in pure and stable form would fulfil an ambition long cherished by organic chemists, and confirmation of the new work will therefore be awaited eagerly. Meanwhile the claim made by the Dutch workers [11] to have synthesised the acid corresponding to vitamin A may perhaps be still more interesting to those studying the vitamin from a biological angle. This acid appears to have a potency equal to that of vitamin A when it is administered orally as the sodium salt.[12] It is said to differ in two ways from all other substances having vitamin-A activity: (1) even large doses do not give rise to storage of vitamin A in the liver [13]; and (2) subcutaneous injections of the sodium salt are only slightly inferior in biological activity to the same doses given orally. These two findings, if confirmed, will have bearings both on our knowledge of vitamin-A metabolism and on vitamin-A therapy in diseases where intestinal absorption is impaired.

Annotations

TO BE CONTINUED

FOR fifty years the voluntary hospitals of Lond have been largely sustained by King Edward's Hospi Fund, which, particularly in time of crisis, has afford indispensable support. Now that the maintenance c is no longer to be borne by private purses, the fu is preparing for a different, though no less valuab allocation of its resources. At a council meeting h at the House of Lords on Dec. 8 H.R.H, the Duke Gloucester pointed out that money given to particul hospitals will enable hospital committees to do ma things impossible within the limits of a strict budg "and we are confident that the flow of voluntary gi will continue." The fund, he said, was concerned wi much that was going to influence the quality of t future service: the training schemes for administrat caterers, and domestic supervisors were being develope and that for administrators had already proved a gre success. Moreover, the fund's work for the recrui ment of nurses continued to augment the efforts of t individual hospitals; and the Emergency Bed Servi was still expanding.

Sir Wilson Jameson, as chief medical officer of t Ministry of Health, remarked that the Ministry and t various boards and committees charged with organisi the National Health Service will have their hands fu "and it is here that the importance lies of having a organisation independent of the Government but workin happily with them." With its progressive and enlighten policy in recent years, the fund had led the way in suc matters as the Emergency Bed Service, nursing recruitment, training bursaries, and convalescent homes, an these were pointers to future possibilities.

EARLY RECOGNITION OF RHEUMATIC HEART DISEASE

WE are still curiously ignorant concerning the incidenc of rheumatic heart disease and its early signs. The mas examination methods of war-time provided a uniqu opportunity to stop these gaps in our knowledge, and Parkinson and Hartley [1] have analysed their findings in 2500 men referred by medical boards in 1940–45 becaus of suspected heart disease. Of these men, 806 were found to have heart disease, and in 609 of them (i.e., 76%) rheumatic heart disease was diagnosed. This ratio of rheumatic to non-rheumatic disease closely follows the American figure, for Wilburne and Ceccolini [2] found that heart disease accounted for 6% of the rejections of recruits on mental or physical grounds, and that 63% of the cases were rheumatic. In the hospital population as a whole Bruce Perry [3] found that 38% of heart cases were rheumatic.

In the recognition of rheumatic heart disease Parkinson and Hartley place greatest reliance on radioscopy and a careful examination, including auscultation with the patient erect (or sitting), lying on his back, and lying on his left side after exercise. The history is also important, but it is unreliable because it can easily be falsified. Routine electrocardiography was soon discarded because its value was found to be limited except in specially difficult cases or those with arrhythmia. Of the entire group, 264 (i.e., 32% of all rheumatic cases) had mitral valvular disease, 184 of these having mitral stenosis and 12 mitral incompetence, while in 68 the diagnosis was "mitral valvular disease probable." Of the 184 recruits in whom mitral stenosis was diagnosed, 104 had a presystolic murmur, 13 a mitral diastolic murmur, 5 a loud apical first sound, 2 no auscultatory abnormality

Special Articles

DIET AND DISEASE IN THE SUBARCTIC

A. C. DUNCAN
M.D. Manitoba
PHYSICIAN, ST. MARY'S HOSPITAL, DAWSON CITY,
YUKON TERRITORY

This article was prompted by a trip "outside" some years ago. At that time, after ten years of general practice in the Yukon, I once again saw children crippled rheumatic fever, again heard the words mitral stenosis, chronic nephritis, and toxæmia of pregnancy. It was then that I fully realised that these afflictions do exist in my section of the far north.

Having determined to record these peculiarities, I [illegible] three years in confirming my original observations. [illegible] been my opportunity to follow and observe a rather unique natural experiment.

Profitable mining at Dawson has held 1500–2000 people [illegible]ally isolated and surrounded by vast sparsely inhabited lands. For the past fourteen years it has been pleasure and responsibility, at times with one substitute, to administer complete medical and surgical to this community. The area involved is provincial [illegible], and consequently it is almost impossible for people to go outside for anything but the most serious of [illegible] surgery. The nearest large centre is Edmonton, far south of us as Winnipeg is east of Vancouver (half the width of Canada). This situation leaves me work of what might be called a "totalitarian" general practice; the residents must see me, and I must treat them, for everything from cataracts to dandruff.

This group of people is subjected to an environment that is unique and constant. Consequently the incidence disease therein may with reason be attributed to the presence or absence of factors that differ from other parts of Canada. For one thing, the diet is certainly unusual, and nutrition alone may explain some of the facts about to be related. Every person in the community, wealthy or poor, has about the same diet. There are no slums here, nor can the well-to do avoid [illegible] physical activities commonly called chores. It is unusual here to see stout flabby men in any walk of life. The tough arctic winter treats all classes with equal disrespect.

RHEUMATIC FEVER

Rheumatic fever does not exist in the Yukon. For fourteen years I have tried to find a typical case, but without success.

There are 350 children in this area under fourteen years of age. This is the number of children named in Santa's list at last year's Christmas tree. This figure does not include very small children or adolescents over fourteen years of age. If these groups are included, the population at an age susceptible to rheumatic fever is much larger than 350. Most of these children I delivered myself; many of them I circumcised, immunised against diphtheria, and operated on for tonsils and adenoids; a few I have watched slip into the oblivion that awaits all.

In such circumstances it is not likely that cases of acute rheumatic fever would be missed. To repeat, to my knowledge the Dawson and Klondyke districts of the Yukon have no case of acute rheumatic polyarthritis, rheumatic myocarditis, pericarditis, or endocarditis; nor has there been any case among the permanent residents. In contrast, general statistics indicate that about six cases should be found constantly in our population. Furthermore, one rheumatic "cardiac cripple" that came here from the outside improved remarkably in a few months and had no acute remissions. He is now working in a garage.

Chorea is not seen. Our northern children have the usual or higher incidence of acute tonsillitis, septic throats, quinsies, and upper respiratory infections. The streptococcus is just as big a nuisance here as in the larger centres. Tonsils are as large, septic, and alluring to the surgeon here as elsewhere. Crowding and poor housing are said to aggravate this disease. In the Yukon housing, on the average, is extremely poor, and usually the children of large families sleep and live in very small cabins. Large houses here are expensive to build and very expensive to heat.

It is also claimed that climatic extremes produce or influence the incidence of rheumatic fever. The Yukon has a very severe climate, with temperatures ranging from full summer heat to a dark dayless 70° below zero, and yet has no rheumatic fever. Since this disease ranks among the first three causes of death in childhood, any light thrown on its ætiology is important.

TOXÆMIAS OF PREGNANCY

In this Yukon district there have been some 400 babies born in the last fourteen years. I have done urine analyses and taken blood-pressure readings on each mother at least six times prenatally. In cases of twins, hydramnios, or those otherwise likely to be toxæmic, more frequent examinations were made. It is very rare to have any woman show albumin to the salicylsulphonic-acid test. The Indians never become toxæmic. Only one patient in my experience had eclampsia. She was not seen before labour, the convulsions atypically starting four days postpartum. This is the only serious toxæmic case in my memory or records. The rarer types of toxæmia, such as acute yellow atrophy of the liver, have never occurred. Moreover, premature births are very rare. Since this is the commonest cause of infant mortality, the latter is very low. Our babies here just don't seem to come too soon.

People in the Yukon consume a great deal of alcohol, but cirrhosis of the liver is very rare; I can recall only one case. To my mind, they also stand surgical shock much better than do their relatives outside. This is especially true of the Indians, in whom the gravest operations cause but slight shock.

NEPHRITIS

That large group of kidney diseases known as Bright's disease, or, better, glomerulonephritis in its three stages, along with its related nephrosis, is unknown in the Yukon. Albuminuria here means usually pyelonephritis or, if in an Indian, a tuberculous kidney. We do not see children with acute nephritis or adults with the usual wet and dry kinds of nephritis. Even the old people with hypertension, which is very common, almost invariably die of cerebral accidents or congestive heart-failure; almost never of uræmia.

Incidentally, we have an overabundance of elderly people in the Klondyke who came here in the days of '98. On the average, I am sure, they live a good decade past their allotted span, unworried about their kidneys and relatively free from those atheromatous patches that ultimately finish most of us.

DIET

What can explain the immunity of this isolated colony of people to these apparently unrelated diseases? I have wondered for years. What element in our lives can explain these facts? The only plausible explanation is diet.

During an average year the residents of Dawson and vicinity eat about 100 tons of imported meat and some 40,000 eggs. There is also available to them an unlimited quantity of wild meat—moose, caribou, rabbits, and fish. Consequently, the poorer the people financially, the more meat they eat relative to the expensive starchy simultaneously in Norway and America in 1899,[4] though the original observations are dated Sept. 2, 1896. The man was then 36 years old. On his face, trunk, and extremities he had numerous cutaneous nodules; some of them flat and others protruding; they were sharply limited, and brown or yellowish-red; some showed fine telangiectasia and slight scaling. There was a considerable amount of lymphadenitis. In the summer of 1940 this patient, then aged 80, was admitted to one of Professor Salvensen's beds in the hospital of Oslo University, suffering from a hypernephroma of the left kidney with metastases in the right kidney and the left lung. There were no demonstrable symptoms of Boeck's sarcoid, nor did necropsy reveal changes which might be so interpreted; but in the skin of the face, especially the forehead and temples, there were slight scar-like alterations with some telangiectasia, while on the tip of the nose there were some yellowish spots which disappeared on pressure with a glass. The swelling of the lymph-glands had completely subsided. Nevertheless the Kveim reaction was positive.

This test for sarcoidosis is not widely known in Britain. In 1941 Kveim[5] demonstrated that a heat-sterilised suspension of sarcoid tissue, taken from a proved case of Boeck's sarcoid, could provoke a slowly forming, indolent papule when injected intracutaneously into a patient with the same malady; the sarcoid tissue is best obtained from a lymphatic gland. The papule persists for several months and may break down to form an indolent ulcer. The test is said to be very reliable.

HEROIC SURGERY

In an account[6] of 100 operations for advanced abdominal cancer, Prof. Alexander Brunschwig, of Chicago University, records performances which will seem almost incredible to older surgeons and may startle even the younger men. His book has been written to recommend radical surgery for conditions generally deemed inoperable; but only a superb craftsman could have contemplated such heroic attacks as are described. For example:

> A patient of 39 had a carcinoma of the splenic flexure. To eradicate it, three-fifths of the stomach, the spleen, the splenic flexure and part of the transverse colon, and most of the body of the pancreas were removed. The patient was discharged with a colostomy on the sixty-second post-operative day; five months later his colostomy was closed. A year later an incisional hernia was repaired, and two and a half years after his operation he is still well.
>
> A patient of 46 with a polypoid carcinoma of the upper part of the stomach had the whole of this organ, the spleen, and the pancreas to the left of its neck, all excised in one piece. He lived for over five months. In another patient, aged 28, the whole of the stomach, a large piece of the left lobe of the liver, the body and tail of the pancreas, the spleen, the transverse colon with all the omentum, and a part of the anterior abdominal wall measuring 12 × 9 cm. were removed. The author believes this to be the most extensive resection on record for neoplastic disease. The patient lived for nearly eight weeks.

How were these great operations possible? Only through the most exact care in preoperative preparation. Blood-transfusions were given whenever the red-cell count was below 4,000,000 per c.mm.; dehydration was always corrected; and a daily urinary output of 1000–1500 ml. was insisted on. Where there had been vomiting, blood-chloride estimations showed whether chlorine was needed. Deficiencies of vitamin K and vitamin C were made good. Great stress was laid on the plasma-protein level: if this was less than 6 g. per 100 ml. the loss was made up by plasma transfusions. Castor oil (1–2 oz.) and 50% magnesium sulphate (2 oz.) we given on the third and second day before operating, get the alimentary canal empty. After operation t maintenance of fluid balance was held to be of gre importance, while nitrogen balance was maintained infusion of protein hydrolysates. Sulphonamides a penicillin were not regarded as of much value for t prevention of infection.

What was the result of this active operative treatme of advanced cancer patients? Of the 100 patien 34 died as the result of the operation; 17 lived, with palliation, up to five months and then died of th disease; 30 lived up to eighteen months after operati and then succumbed; 6 lived for an average of thirt three months; and 13 are living with an average surviv of forty months.

Clearly it is difficult to assess the usefulness of su undertakings. As the operations become greater a greater in extent there must come a stage beyond whi the patient, though surviving, is so handicapped that h life is a burden, but where are we to draw the line In some instances there is no question, because relief great; for example, where a massive growth is obstruc ing the pylorus, gastrectomy may give relief even thoug there are secondary growths in the liver. But whe massive parts of the body are removed, defects in functio not always measurable, must remain. How many these 100 patients were thankful that the operation w done we do not know. Admittedly it is necessary keep extending the limits of what is surgically possibl but even in successful cases the general enfeebleme caused by a large abdominal operation lasts for month It would have been instructive to have the postoperati happiness of these patients assessed by an unbias social worker.

POSTGRADUATE TRAINING IN EIRE

Though the new Health Act, lately passed aft three years' resistance, is now being challenged in th High Court by Deputy Dillon as being repugnant t the constitution of Eire, the department of health i going ahead with its development plans. The Medica Research Council grant has been doubled, a tuberculosi chemotherapy research unit has been set up, tuberculosi training courses have been organised, and teams ar shortly to be sent abroad for further training. In th past, though many million pounds from the Hospital Trust Fund have been spent on building and equipment little has gone to training men. Now the minister fo health proposes to establish a postgraduate centre fo medical officers of local authorities, which will be locate at St. Kevin's Hospital, a large poor-law infirmary in Dublin. He has also appointed a committee to examine the present system of undergraduate and postgraduate education, and to make recommendations on changes required in the curricula and organisation of medical education, on the consolidation or amendment of the Medical Practitioners Act, 1927, with special reference to the control of medical education, registration, discipline, and reciprocity, and on any further arrangements to be made for specialist research in medicine and allied sciences.

LONDON'S HEALTH SERVICES

Some of its duties under the National Health Service Act were considered by the London County Council last Tuesday. Personal health services are to be administered in nine divisions, each headed by a senior medical officer. These divisions are to be subdivided into 165 areas, each containing about 20,000 people and composed of two or more neighbourhood units. The ultimate aim is to provide for each area a comprehensive health centre, including general-practitioner service, which will be within about a mile of every user's home.

[6] Radical Surgery in Advanced Abdominal Cancer. By ALEXANDER BRUNSCHWIG, M.D., professor of surgery, University of Chicago. London: Cambridge University Press. 1947. Pp. 324. 42s.

Rheumatic fever, glomerulonephritis, nephrosis, and toxæmias of pregnancy can all be regarded as reactions protein-starved connective tissue to metabolites of ection.

Experience in the Yukon suggests that rheumatic r would cease to exist if every child ate an egg daily from babyhood, that toxæmias of pregnancy would be virtually eliminated if every pregnant woman took a pound of meat daily, and that some of the degenerative diseases of the kidney could be prevented by adequate protein intake throughout life.

WORLD FEDERATION OF ASSOCIATIONS OF CLINICAL PATHOLOGY

An international association of societies devoted to that branch of medicine known in this country and the United States as clinical pathology was brought into being at meetings held in Paris on Nov. 21 and 22 during the first international congress of the Société Française de Biologie Clinique. The conference had been called under the presidency of Prof. Michel Polonovski, of Paris; but at its opening Professor Polonovski, in courteous recognition of the pioneer work of the European Association of Clinical Pathologists, invited its president, Dr. S. C. Dyke, of Wolverhampton, to occupy the chair, and the remainder of the proceedings were conducted under the chairmanship of Dr. Dyke. Delegates and observers attended from Belgium, Czechoslovakia, Denmark, France, Great Britain, Greece, Italy, Peru, and the United States.

The term "clinical pathology," though long employed and well understood both in Great Britain and the United States, is not in general use in many Continental countries, while in others it carries meanings differing from that accepted in Britain and the United States. The conference, therefore decided to adopt for international usage the name "clinical biology," this being defined in the terms used by the European Association of Clinical Pathologists as consisting in "the application of pathology and all its related sciences to clinical medicine." The objects of the international association were defined as the establishment of permanent coöperation between the member national societies of clinical biology; and the coördination of their scientific and technical means of action and the furtherance of clinical biology in every aspect of its field by convening conferences, congresses, and meetings and by interchange of publications and even more especially of personnel.

The conference had before it texts of proposed statutes prepared both by the Société Française de Biologie Clinique and by the European Association of Clinical Pathologists. Although prepared independently, these showed a surprising degree of conformity, and in the course of two sessions the conference was able to draw up a provisional constitution. This was designed in general conformance to the rules established by UNESCO for its associated international bodies; it establishes the governing body of the International Federation as a council or commission of the delegates from the national member societies. This council acts through the executive committee elected by itself and consisting of six members. The English and French texts of the statutes will come up for ratification at a full meeting of the council, which, it is hoped, will be held in England in the course of the next summer gathering of the British Association of Clinical Pathologists.

The conference elected its officers as follows: president, Dr. Dyke; vice-president, Prof. Raoul Kourilski (France); secretaries, Dr. A. Durupt (France) and Dr. J. Ungar, (England); treasurer, Dr. W. H. McMenemey (England). The second office of vice-president was left vacant in the hope that it might be filled by a representative of the United States of America.

National societies devoted to clinical biology and wishing to become members of the international association are cordially invited to communicate with either of the secretaries, Dr. A. Durupt, 20, Rue de la Pompe, Paris, or Dr. J. Ungar, Glaxo Laboratories, Greenford, Middlesex.

A MODERN MATERNITY HOSPITAL

WHEN the old Jewish Maternity Hospital withdrew from its site in Whitechapel, during the war, it gave birth to two daughter hospitals, one at Hampton Court and the other at Stoke Newington. The Bearsted Memorial Hospital at Stoke Newington, named after the parents of the present Viscount Bearsted, who did much to establish it, was actually begun before the war; and though far from complete—it still lacks its upper stories and much of its projected ground plan—it is as fine an example of a maternity hospital as we have to show in this country just now. The new building, which was officially opened by Viscountess Bearsted on Dec. 17, has been in action since last August, and takes 24 mothers in the public wards and 6 in private rooms. Though specially designed to respect Jewish customs and dietary laws, it is open to mothers of all creeds; nor is any discrimination shown in appointing staff.

The main door opens into a warm light waiting-hall, provided with comfortable chairs and a couple of desks at which visitors write notes to patients if they cannot go in to see them. This hall gives the note of the whole hospital, which somehow manages to be airy and spacious, yet intimate.

IN THE WARDS

The wide corridor to the wards is interrupted by a low swing gate of black wood dividing the administrative side from the hospital proper. It has the effect of reminding people that they are entering regions where such things as infection and noise must be kept in mind.

Single-bed private wards open from it, each with its wash-basin, well-sprung bed, and broad Crittall windows which fold back to leave almost a whole wall open to the air—a pleasant thing in summer, for the garden lies outside, and a striped awning can be lowered above the window, to keep the room cool and intercept glare. The light is placed above the bed but to one side of it, so that it cannot shine directly in the patient's eyes; and she can either switch it full on, or dim it to the power of a night-light. If she needs anything, a bedside button sets a buzzer going and lights a red signal in the sister's office, and also switches on a signal light beside the bed which remains burning until the nurse coming to attend her switches it off. Signals of the same type are fitted in the bathrooms.

The main wards are all small—either 2 or 4 beds in each—and are as comfortably equipped as the private wards. All are delicately coloured, with softly tinted ceilings, easy to the eyes.

WORKROOMS

Besides a strong central light, each of the two labour wards has, depending from the ceiling towards the foot of the bed, a powerful bulb set at the end of a long telescopic arm, which remains steady in any position to which it is pushed. The bulb, in its conical shade, can be twisted about on the end of this arm until the light is directed as the doctor or midwife needs.

A ward is provided in which two mothers in the first stage of labour can keep each other company through the tedious early hours. When the upper stories are complete, and the hospital reaches its full complement of 100 beds, it will be possible to convert another small ward, at present being used as a private room, into a third labour ward.

The two sluice-rooms are fresh, light, and warm. Stainless steel bed-pans are placed, after use, straight into a mechanical cleanser, which washes them clean and sterilises them with steam. On removal they go into a rack composed of hot pipes, which keeps them at a suitable temperature. Bed-pans are numbered, each patient keeping her own throughout her stay in hospital; when she leaves her pan is sterilised thoroughly before being given out again.

THE NURSERIES

There are four nurseries: a large one, in which the babies in their cots are protected by a glass screen from gusts of air or organisms disseminated by those who enter hurriedly; another of medium size; a small one, for premature babies, which no-one may enter unmasked; and a small isolation nursery for babies isolated because they are suspected of developing an infection. Some of the cots are made in open wire-work, others are smooth-walled receptacles painted in light colours, in which the babies look like something just foods. The converse is true of the diet in the larger populated centres outside. In the Yukon the starches and sugary foods are expensive because of transport costs, whereas fresh meat is to be had by anyone with a bullet and a strong back. As so-called civilisation advances, human beings eat more and more of the fuel type of foods—i.e., carbohydrates and fats. To their detriment they ingest less and less of the all-important reparative protein foodstuffs.

One summer an Indian fell out of a tree, injuring his neck. I made a trip by aircraft to an isolated lake in the western Yukon to investigate. Upon arrival I learnt that the unfortunate man had died the day before. However, the trip gave me a chance to see a group of Indians who were the subject of an involuntary dietary experiment. The whole village complained bitterly that they were starving, having had no flour, tea, or other store food for some months. To my amazement the whole tribe was fat, alert, and generally in excellent physical shape. Even the babies and small children (some gnawing boiled fish-heads) were energetic, a good colour, mischievous, and acting as healthy children should. At the lakeside there were stacks of fresh whitefish netted in the nearby bay. These people had survived—yes, thrived—on an exclusive, if involuntary, fish diet for months. They eat not only the muscle tissue but also the livers, heads, spleens, and whatever else a fish has.

Practically no northern Indian likes agriculture. Occasionally a man will, if persuaded, plant a few potatoes, but they much prefer to hunt and eat meat. Most Indians regard working in the soil as degrading and undignified.

—AND DISEASE

During my whole time in the Yukon I have seen only two cases of cancer in the Indians, both of them in women married to white men living in town and eating our diet. Is it possible that the glands and entrails of fish and animals provide an immune factor ?

It has been shown that the quality of meat depends to a large extent on the food of the animal producing the meat. The same is true of eggs; the hen produces an egg rich or poor nutritionally, according to her diet. Our Yukon protein intake is largely of natural food. The animals eat the native mosses, grasses, and lichens, and not the chopped farinaceous matter of a depleted soil, as is the case with domestic animals. Maybe this natural diet produces a better grade of prophylactic protein. Possibly, also, a superior egg comes from a hen that eats plenty of beetles. It is said that migrating ducks and geese go north because of a craving for some substance found in northern lichens.

Man's gut, I believe, is essentially and basically carnivorous. Our ancestors, like the present-day Indians, did not eat highly processed farinaceous food. Our entodermic tube, with its processing liver and other accessory glands, is set up to receive far more protein than the average present-day human is feeding it. To repeat, we eat too much of the "fuel" foods and not enough of the "building-material" foods.

Rheumatic Fever and Nephritis

Both rheumatic fever and glomerulonephritis are said to be due to, or associated with, the ever-present streptococcus, harboured in septic teeth and tonsils and elsewhere. Yet in both diseases no streptococci are found at the site of the lesions, which are therefore regarded as reactions to diffuse toxins, possibly acting allergically.

Consider now the similarity in this diffuse reaction. Both diseases affect connective tissues essentially, and both cause a proliferative and exudative reaction. In glomerulonephritis the primary lesion is a swelling and proliferation of the endothelium of the glomerular tuft vessels, leading to obliteration of the circulation. The Aschoff body of rheumatic fever is also a group of swollen and proliferating cells of the self-same reticulo-endothelial system; essentially the same kind of cellular reaction in the kidney and the heart. In glomeru nephritis the swollen tufts cut off the circulation to glomerulus, and this is followed by secondary hyal and tubular degeneration. In rheumatic fever sim degeneration is succeeded by useless scar tissue an ruined heart. The end-result of glomerulonephritis often the same burnt-out mass—a granular contrac kidney.

The exudative factor in rheumatic fever is well kno typically causing the large swollen joints and nodu In glomerulonephritis the second stage is characteri by the "large white kidney." Is not the œdema nephritis simply exudation in the extreme ? This œde could be due to a similar degeneration of the capill endothelial cells or their cement substance, allow fluid to pass to the tissues. A similar failure in per ability in the kidney glomerular cells could expl albuminuria.

Shock itself may be partly due to increased en thelial permeability. Does not a plasma transfus amount to a protein rejuvenation ? The pure osm *advantage of the protein molecules in the circulat* is not the whole explanation of such a transfusi otherwise acacia solutions of the same osmotic read would be as effective as plasma in shock. I suggest t blood-protein transfusions, besides helping mechanica by attracting electrolytes and fluids to the circu tion, are also chemical aids in repairing the inju capillary cells. This may be the reason why prote rich Yukoners do not readily suffer surgical shock.

Arterial Degeneration

The subintimal thickening, endothelial proliferati degeneration, fibrosis, and ultimate ischæmia of athe sclerosis are also suspiciously like the pathologi conditions I have just mentioned. To hazard a pur speculative thought perhaps the dietary habits of most civilised communities have a lot to do with th prematurely narrowed tubing and all its dire consequen

Incidentally, most of the progress in modern medic is being made in the acute bacterial diseases. Could not spare a little more time for the less spectacula but really more important, degenerative disease Personally, I am more concerned about the insidio progress of my coronary plaques than anything else medicine.

I fully realise that many of the pathological poin made above are subject to question. However, aft consideration, it seems to me likely that persiste dietary protein deficiency leads to a uniform pathologic lesion in the reticulo-endothelial system with hyper plasia, degeneration, and ultimately substitution b scar tissue. It may well be that these tissues, adequatel protected by protein intake, are immune to the constantl recurring minimal doses of toxins, whether from strepto cocci, pregnancy, alcohol, or other cause. Unprotecte and undernourished tissues, conversely, react typicall to these stimulants and develop the clinical disease mentioned. The microscopical and clinical pictures o rheumatic fever and nephritis may at times sugges inflammation; but some of the deficiency diseases— e.g., beriberi—were also regarded as inflammatory befor their true nature was known.

Be all this as it may, the Yukon diet is very rich in natural proteins, and this I offer as the explanation for the absence of several important diseases.

CONCLUSION

In an area of the Yukon, lying in the subarctic region, the inhabitants do not suffer from rheumatic fever or glomerulonephritis, while toxæmias of pregnancy are very rare.

These people take a high-protein diet, including much meat.

ship agreements, it is also impossible to estimate at the appointed day the shares due to individual partners. This being so, it is impossible to carry out the requirement of the Act that interest should be paid annually to individual practitioners.

A practitioner may be required (*a*) to buy a partner's public practice the capital value of which he cannot realise, the income from which he cannot receive, and compensation for which is not available to him: or (*b*) to buy a partner's private practice which he cannot sell and in respect of which no compensation is payable from the monies provided under the Act.

The assumption that it will be possible to estimate the shares of individual practices (as distinct from individual practitioners) is probably unfounded; for the Act requires, in theory, that the whole of the £66 million, or the appropriate proportion thereof, shall be paid out, and in practice there will be an undistributable residue. The Government cannot keep its promise in regard to the relief of hardship, and at the same time put into operation the Act in its present form.

If the Ministry's interpretation is correct, unfairness amounting in some cases to expropriation will result, and practitioners desiring to remain outside the service may in self-protection be forced into it. On the other hand, if this interpretation is wrong (as Sir Cyril Radcliffe, K.C., and Mr. J. H. Stamp believe) a practitioner who fulfils his obligation to buy or sell a share will be liable to a fine or imprisonment or both. A final ruling on this matter can be given only by the House of Lords, and meanwhile no practitioner can be sure of his position. It is unjust to leave a demonstrably ambiguous Act unamended, and the financial situation of practitioners uncertain, until a case has been fought out in the courts. Doctors who do not join the service by the appointed day do not qualify for compensation, and for this reason alone the position should be precisely defined at least six months before that day.

It is in the best interests of the public and the profession that general practitioners should retain the ownership of the goodwill of their practices. This ownership provides an important incentive, encourages good and keen work, provides a basis for coöperation between practitioners and a bond between doctors and their patients. Although emphasis is laid in this statement on the unworkability of the Act in this respect, the issue of ownership of goodwill is regarded by the medical profession as fundamental to its freedom.

Partners and Assistants

In partnerships formed after the appointed day and involving a practice in the public service it will be illegal for the partners to distribute the emoluments except in the proportion in which they are earned: a sale of goodwill is deemed to have taken place where "services are performed by any partner for a consideration substantially less than those services might reasonably have been expected to be worth having regard to the circumstances at the time when the agreement was made." Since it is hard to assess the "worth" of the services of either a senior or a junior partner, and their respective value is liable to change, the general effect will be to discourage partnerships. It is ironical that an Act which aims at the development of group practice should do this.

Similarly, a practitioner who pays an assistant substantially less than his services "might reasonably have been expected to be worth" and who afterwards admits the assistant to partnership commits an offence. In this way the Act discourages practitioners from admitting assistants to partnerships, and hence discourages the newly qualified doctor from doing what is highly desirable he should do—namely, serve as an assistant before he becomes a principal. More and more practices will be left with no-one in charge when a principal dies or retires.

It may be argued that the system of registration of agreements with the Medical Practices Committee will protect the profession from the above dangers. But nothing is known about the attitude which this committee may adopt. And however much the committee may desire to do nothing to endanger partnerships and assistantships, or to endanger practitioners, it cannot act except in conformity with the statute.

Remuneration

The committee hold that, except in special circumstances, the remuneration of general practitioners should be by capitation payment in proportion to the number of persons on a doctor's list, and that this principle, which they regard as fundamental, should be embodied in the Act. They are opposed to the payment generally of a salary, basic or other.

The remuneration of specialists for hospital work should be on the basis of annual payments. Specialists should be free to decide whether they will undertake domiciliary work, and those who do so should be paid according to items of service rendered.

Midwifery

By imposing a qualification in addition to the statutory qualification the Minister has taken power to restrict the right to participate in the midwifery services. This is unnecessary and undesirable.

Nursing-homes, Hospitals, and Private Patients

It is undesirable, too, that the Minister should be empowered to establish a monopoly in hospitals. State-ownership of nursing-homes would tend to deprive the profession of facilities for independent practice, continuance of which is necessary to the maintenance of a high standard of medical service. Private nursing-homes, whether carried on for profit or not, should not be acquired under the Act.

The Minister's discretion should be replaced by an obligation to permit specialists in the service to treat private patients in private beds at their own or any other hospital. To set a maximum on fees chargeable to patients who pay the full cost of private accommodation would be wholly inappropriate. In at least a proportion of private beds arrangements between the specialist and the patient should not be subject to control by regulation.

Administrative Bodies

After the initial appointments, local executive councils, boards of governors of teaching hospitals, and hospital management committees should elect their own chairman.

Local health authorities should be required to coöpt to health committees practitioners representative of the local profession.

Right of Appeal

There should be a right of appeal to the High Court against a decision to remove a practitioner's name from the list(s) of any or all executive councils.

General Comment

In concluding their statement (of which the above is only a brief summary) the committee say that the Act involves an excessive concentration of power in the hands of the Minister, and as it now stands is in many respects unacceptable to the medical profession. It is full of legal perplexities and anomalies which could only be resolved, if at all, after prolonged litigation accompanied by widespread uncertainty among the profession and the public. Many of its provisions are fraught with the risk of grave hardship to patients and with serious injustice to doctors and their dependants. Even with the utmost good will on the part of the medical profession its wording is in places so obscure that to bring it into force as it stands will create chaotic conditions.

delivered by an expensive florist. Cots of the second type are preferred by the nurses because they protect the child from draughts, are easy to clean, and, unlike the wire cots, have no tiny projections which catch at clothes and shawls.

The babies' baths, in the nurseries, are specially made without taps; a faucet, set in a recess at the back of the bath, is controlled by a pedal near the floor which the nurse operates with her foot. The water it releases into the bath is at a suitable temperature, controlled by a thermostat. The baths, set at a convenient height for the nurse, have tables at their side on which the babies can be laid while they are dressed; and each baby keeps its soap and flannel in a box at the foot of its cot.

THE THEATRE

At one end of the block is a spacious and well-lighted theatre, one wall and part of the roof being of glass. The light over the table is provided by a series of fluorescent tubes, which give a brilliant almost shadowless light. Emergency lamps, running off a battery, are set in the same frame and come on automatically if the main lighting fails. All electric switches are mercury controlled, which rules out danger from sparks.

A small changing-room for the operating gynæcologist and his assistant is fitted with a shower, set at a height which sprays the shoulders and spares the hair.

KITCHENS

The ward kitchens are divided down the middle, all equipment (gas-stoves, refrigerators, cookers, and sinks) being duplicated in the two halves. This makes it possible to respect the Jewish dietary law requiring meat and milk to be prepared separately. Bottles are cleaned and sterilised in a small room designed for the purpose, the sink being fitted with a bottle-brush which spins vigorously when a switch is turned.

The main hospital kitchens are in an adjoining block. They are amply fitted to serve the proposed 100 beds of the complete hospital, though the staff will have to be augmented, of course, when that time comes.

The bedrooms of nurses and domestic staff are a welcome sample of democracy in practice. Domestic workers and pupil midwives—there are 14 in training at the hospital—have identical types of room, with cream walls, a first-class bed, a neat dressing-table and wardrobe unit in light wood, and a good-sized recess to hold shoes and coats. Their windows, like those elsewhere in the hospital, are curtained in canvas printed in good designs; and they are well warmed by radiators. A cheerful dining-room has small green-topped tables.

Eight sisters serve on the staff, all doubly qualified as State-registered nurses and midwives; one is reserved entirely for the care of premature and sick babies. They have chosen to live in a converted Edwardian house in the grounds of the hospital, which gives them a sense of being in a home of their own. The rooms are as various as those in a private house, though each has its gas-fire, well-sprung bed, easy chair, wardrobe, dressing-table, and small graceful desk. Tea is served in the common-room, which though pleasant inevitably lacks the character of rooms about which personal belongings are distributed. The preference of these sisters for the old house seems to bear out the experience of the Marie Curie Hospital[1] that nurses prefer variety in their quarters to uniformity, however perfect the uniform level.

"... If it takes six years at the university to qualify in medicine, and then at least three years more after qualifying to get a special diploma (and it will soon take five years after qualifying to become a medical specialist) when is a man going to do any original work? Because really original work is done by people under thirty. . . . The *young men of today* are increasingly aware of the dilemma, that they cannot be both physician and scientist. The young man of today who wants to do active original scientific work has got to turn his back on diplomas and professorships of clinical medicine. And he is turning his back, so that any university today would tell you that it is becoming increasingly difficult to fill clinical chairs with first-class whole-time teachers."—Prof. L. J. WITTS, *Listener*, Dec. 11, p. 1009.

Reconstruction

NATIONAL HEALTH SERVICE

STATEMENTS BY NEGOTIATING COMMITTE AND MINISTER

LAST February a reconstituted Negotiating Committe was appointed to discuss the National Health Service Act with the Minister of Health. The members were:

British Medical Association.—Dr. H. Guy Dain (chairman of the committee), Dr. J. B. Miller, Mr. A. L. Abel, Dr. J. C Arthur, Dr. J. A. Brown, Dr. O. C. Carter, Dr. R. W. Cockshut Dr. W. E. Dornan, Dr. F. Gray, Dr. E. A. Gregg, Lord Horder, Dr. J. A. L. Vaughan Jones, Dr. W. Jope, Dr. J. F. Lambie, Mr. R. L. Newell, Dr. J. A. Pridham, Dr. S. Wand, Dr. S. A. Winstanley.

Royal College of Physicians.—Lord Moran, Dr. H. E. A. Boldero, Prof. Henry Cohen.

Royal College of Surgeons.—Sir Alfred Webb-Johnson, Mr. Zachary Cope, Prof. E. F. Finch.

Royal College of Obstetricians and Gynæcologists.—Mr. William Gilliatt, Mr. A. A. Gemmell.

Royal Scottish Medical Corporations.—Prof. Charles McNeil, Sir Henry Wade, Dr. J. H. Macdonald.

Society of Medical Officers of Health.—Dr. G. F. Buchan, Dr. R. H. H. Jolly.

Medical Women's Federation.—Dr. Mary Esslemont.

Society of Apothecaries.—Dr. H. Seaward Morley.

Association of Honorary Staffs of the Major (non-undergraduate teaching) Voluntary Hospitals of England and Wales.—Mr. H. J. McCurrich.

This week the British Medical Association has sent to every member of the profession a statement in which the committee crystallise their objections to the Act, together with a statement made by the Minister in reply.

Committee's Objections

Distribution of Practitioners

The Minister's arguments for abolishing the ownership of goodwill in public general practice are based on the need for better distribution of doctors. But when, under the Act, the same medical payment will be available for every member of the community, wherever he lives and whatever his status, no area will remain under-doctored through inability to purchase medical service. Any deficiency of doctors in particular localities can be remedied by making the terms of service in those localities more attractive.

The Act's procedure is so cumbersome that three or four months may pass before a practice vacancy is filled, during which time the patients may have attached themselves to the locum tenens or to a neighbouring practitioner. The necessary inquiry into the circumstances of every area places an intolerable strain on the Medical Practices Committee, and this committee's decision not to fill a vacancy may oblige patients to join the list of a doctor they have previously rejected.

Doctors deciding to enter the service should be free to choose their area of practice.

Sale and Purchase of Practices

In the committee's opinion the discussions have justified their original view that "abolition of the custom of buying and selling practices has created more problems than it solves." Almost every existing partnership is governed by an agreement; and, according to the Ministry's interpretation of the Act, all these agreements will remain legally valid after the Act comes into force. If so—

> An individual practitioner may be required to pay out a sum of money to purchase a share, the compensation value of which is less than the amount he has paid.
>
> As it is impossible to estimate in terms of money the various rights, obligations, and options in typical partner-

and provision is in view. Each unit liable to ta is already being given opportunity to advance arguments for its exclusion. In general a nursing-home would have prima-facie grounds for exclusion: and homes run for profit are not transferable at all. The acquisition of a number of small private nursing-homes would be an uneconomic and unsatisfactory way of developing the service.

The Minister intends that all medical members of hospital staffs should be allowed to treat private patients in any private accommodation in the hospital: but arrangements must ultimately depend on local facilities. He is prepared—where circumstances permit—to allow a proportion of private beds to be used without any prescribed maximum for fees to the patient.

Administrative Bodies

The Minister agrees that after the first appointment and executive councils should nominate their own chairmen. Any views expressed by boards of governors and management committees about succession to the chairmanship will be given full weight.

He has no power to compel local health authorities to co-opt non-elected members to their health committees, but he will encourage them to do so.

Right of Appeal

The Minister, being responsible for the service, must decide in the last resort whether it is possible to retain a practitioner whose retention, in the tribunal's view, would be "prejudicial to the efficiency of the service." He could not answer to Parliament for a doctor whom he was forced to retain. Provision will, however, be made for him to consult an advisory committee of the type which has advised on similar cases under the insurance scheme. The doctor has the ordinary legal rights to go to the courts on grounds of unlawful action by the Minister or others.

General Comment

Being responsible to Parliament and the nation, the Minister must have ultimate jurisdiction as to the nature and quality of the service provided. But the Act has gone as far as it justifiably could in providing that he will delegate this responsibility to regional and local bodies in which the profession and others are strongly represented.

The Act will be amended, without doubt: the scheme will be bettered and remoulded as experience is gained. But first it has to be begun if there is to be that experience. The Minister is confident that the mass of men and women working in the medical field now, or about to enter it, will join him in beginning it and in constantly improving it.

Minister to Doctor

The Minister's main statement is prefaced by some general comments addressed to the individual doctor who wants to know how participation in the service will affect him personally.

The term "service," he says, is a misnomer if it is held to imply an organised corps. There is no hierarchy or "supervision" or interference with a doctor's professional judgment and clinical practice: "he undertakes to look after patients and is left to do so in his own way and to the best of his clinical ability." Nor is the practitioner "employed": he enters into a contract which in essence is to look after the patient whose care he undertakes—and to be paid for it from public funds, in these cases, instead of by private fee. He is certainly not a civil servant.

The aim will be to set 4000 as the maximum number of patients for a doctor under the scheme, but there is no finality in this. Any doctor can also retain private practice.

Compensation and Superannuation

Doctors who participate on the appointed day will establish their claim to their share of the £66 million set aside as compensation for their being unable in future to sell public practices. The Minister is prepared to take the profession's advice as to how this should be equitably distributed. Normally, it will be payable when capital values would otherwise be realised—on retirement or death—with interest in the meantime. But if there is hardship, like some undue debt burden on the practice, it can be paid at once. If a doctor wants, later on, to stop practice for any reason he can draw his compensation at once and do so.

In addition, a superannuation scheme is to be started, the doctor contributing 6% of the payment he receives in the new service (less a percentage for "practice expenses") and the Government 8%. The benefits will include a pension and a lump sum on retirement, a death benefit, and a widow's pension.

Assistants

As before, the engagement of assistants, paid by the doctor, will permit of enlarged lists of potential patients. In addition there will be a system of grants to doctors for the training of young assistants.

Health Centres

As and when health centres are set up, no doctor will be compelled to practise in them. In such health centres the personal relationship (of "my doctor") will be retained. They will be a substitute for the doctor's home surgery, publicly serviced and equipped. Group practice, like present partnerships, will be encouraged in them.

Doctors in the Running of the Service

Doctors are, for the first time, brought on a substantial scale into every main field of administration of the new scheme—regional hospital boards, boards of governors of teaching hospitals, and executive councils. It is a new experiment in bringing the profession itself into the direct administration. In addition there is to be a Central Health Services Council, with a majority of doctors (to advise the Minister on the whole scheme), and a special Statutory Advisory Committee of the Medical Profession. Both can advise without being asked and the Minister has to publish the Council's report (save only where the public interest prohibits).

The Object

The object of the new Act is a simple one. It is to help, by public funds, to ensure that anyone—the highest and the lowest—should be confident of getting all the best that a great profession can give. If the profession rally to it, the greatest health service in the world can come into being. There is no reason whatever why the personal relationship of doctor and patient—and the professional independence of the doctor—should be affected by a switch-over from private fees to public funds.

A scheme of this magnitude is bound to need correcting, amending, as it is found wanting. But, in its conception, it is something of incalculable social value to the great mass of the population, and the medical profession will be the first to want—as they have wanted—something of this kind. For his part, the Minister is concerned mainly to get this great national scheme launched, and to plan on wider, better lines, with the profession directly coöperating in the management of the new service. He asks the profession to help him in launching it next year and in constantly improving it as it goes along. It is a big thing, and he is confident that the profession will join with him, as constructive and often properly critical partners, in getting it under way.

Replies by the Minister

In his detailed answer to the committee the Minister says that he sees no sufficient reason for asking Parliament to amend the Act before the new service has been tested in operation.

Distribution of Practitioners

Especially when doctors are scarce, it cannot be assumed that payment in respect of all (or almost all) the people will result in an equal distribution of doctors in relation to population. The new service reserves the right only to say in what areas it has no need for additional participants or replacements. This is the minimum interference with distribution of a public service that could be justified. Without it doctors would have a right to demand publicly remunerated work where they like.

The procedure for obtaining consent to practise will not be as cumbersome as the Negotiating Committee suggest. The Medical Practices Committee, keeping in regular touch with local executive councils, will know the areas where there is no need for new public practice or replacement—and these will be few, for many years to come, until the number of doctors has increased. Apart from such areas consent can usually be given automatically, unless there are two or more claimants for one practice. And, even so, the period of settlement should normally be nearer one month than four.

Sale and Purchase of Practices

The Minister, on all the legal advice he has obtained, believes that partnership agreements will remain valid after the appointed day. If the courts prove his interpretation wrong he will ask Parliament to correct the Act in this sense. In his opinion existing powers or obligations between partners to buy or sell shares of a practice can be fulfilled; regulations can be made which will dispose of all the major difficulties. If on the other hand his advice is wrong, it is always possible for partners to vary the terms of their partnership and so remove anomalies which cannot be covered by any general provision. Likewise, partners who anticipate difficulty over the future purchase of shares under the partnership agreement could agree among themselves that the price to be paid for such shares shall be the same as, or not exceed, the compensation assessed in respect of those shares. It appears most equitable to pay the interest to the owner of the asset for the time being.

A partner within the service, required to buy the share of a partner not in the service, will receive compensation for the share so bought, on the basis of the value at the appointed day. The effect of this will be payment of compensation for which there is no provision in the aggregate amount of compensation. On the other hand, when a partner not participating in the service buys the share of a partner who is in it, compensation in respect of that share will no longer be payable to the partner in the service, since he will have suffered no loss. Here there will be non-payment of compensation for which there is provision in the aggregate. For the time being the Minister proposes to assume that the excess and the saving in these two instances will balance one another. The balances can hardly be exact and will need later adjustment.

If the total amount provided for compensation proves insufficient because all general practitioners join the service on the appointed day, the Minister will ask Parliament to increase the global sum appropriately.

Partners and Assistants

The main object of new partnerships formed after the appointed day will be greater convenience and better facilities for practice. The remuneration of each partner must be assessed on the general basis of his value to the partnership, and can take account not only of his earnings but of his knowledge, experience, and standing. There seems to be no reason why this basis of partnership should discourage partnerships in future, or why the buying and selling of shares should be regarded as the essence of a partnership in medical practice.

As for assistants, an offence will be committed only if the assistant is paid so obviously less than he is worth as to amount to a sale of goodwill. In case of doubt a certificate from the Medical Practices Committee gives a complete safeguard. The Minister agrees with the committee about the desirability of an initial period of assistantship, but cannot think that the difficulties they anticipate are likely to arise.

Remuneration

To translate the recommendations of the Spens Committee into actual terms of remuneration for general practitioners the Minister proposes to establish a central fund equal to a capitation fee of 18*s*. multiplied by 95% of the population. (This 95% will be reconsidered after two years, having regard to the number of people found to be using the service.) On this fund there will be a first charge for (*a*) mileage, fees for temporary residents, emergencies, and anæsthetics, and (*b*) a fixed annual payment of £300 to every practitioner who accepts a reasonable number of patients. The rest of the fund will be distributed to each executive council on the basis of a capitation payment multiplied by the *number of people on the doctor's lists plus one-third of* the number not on the lists. This will then be distributed among the doctors of the area in the form of a capitation fee for each person on his list.

In addition, a sum equal to 1% of the central fund (about £400,000) will be attached to the central fund to enable extra "inducement" payments to be made to doctors practising in peculiarly difficult (e.g., sparsely populated or unpopular) areas. On these proposals:

The estimated civilian population of Great Britain at June 30, 1948, is 47,750,000.

Therefore 95% of this number is 45,362.000.

A payment at the rate of 18*s*. per head of this number would produce a central fund of £40,826,250.

Assuming 17,900 principals take part in the service the deductions to be made from this amount would be:

(*a*) Mileage payments, say	£1,000,000
(*b*) 17,900 fixed annual payments of £300	£5,370,000
	£6,370,000

Leaving a net amount to be distributed of £34,456,250.

If the full 95% of the population were actually on doctors' lists the payment per head (additional to the £300 fixed sum) would still be about 15*s*. 2*d*. The gross income (inclusive of receipts from private practice, obstetric service, mileage, &c.) would be:

1000 public patients ..	£300 + £758 = £1058
2000 ,, ,, ..	£300 + £1516 = £1816
3000 ,, ,, ..	£300 + £2274 = £2574
4000 ,, ,, ..	£300 + £3032 = £3332

There would also be a pool of £408,262 available for "inducement" payments.

Remuneration of specialists will be considered with the profession when the report of the Spens Committee on Specialists is received. The Minister considers that specialists should, as widely as practicable (though not universally), accept as part of their duties domiciliary work within defined limits.

Midwifery

Within the service, general practitioners who express a desire to practise midwifery and answer calls from midwives will be asked the extent and nature of their obstetrical practice during the preceding three years. Their particulars will be placed before a local professional committee which will compile (and periodically review) the local list.

Nursing-homes, Hospitals, and Private Patients

The Minister is under obligation to provide an adequate hospital service, and he must clearly have transferred to him all existing hospitals essential for the provision of the service now, with powers to acquire land and premises in future. But no absolute monopoly of ital provision is in view. Each unit liable to fer is already being given opportunity to advance reasons for its exclusion. In general a nursing-home would have prima-facie grounds for exclusion: and those run for profit are not transferable at all. The acquisition of a number of small private nursing-homes would be an uneconomic and unsatisfactory way of developing the service.

The Minister intends that all medical members of hospital staffs should be allowed to treat private patients in any private accommodation in the hospital; but arrangements must ultimately depend on local facilities. He is prepared—where circumstances permit—to allow a proportion of private beds to be used without any prescribed maximum for fees to the patient.

Administrative Bodies

The Minister agrees that after the first appointment local executive councils should nominate their own chairmen. Any views expressed by boards of governors and management committees about succession to the chairmanship will be given full weight.

He has no power to compel local health authorities to coöpt non-elected members to their health committees, but he will encourage them to do so.

Tribunal of Appeal

The Minister, being responsible for the service, must decide in the last resort whether it is possible to retain a practitioner whose retention, in the tribunal's view, would be "prejudicial to the efficiency of the service." He could not answer to Parliament for a doctor whom he was forced to retain. Provision will, however, be made for him to consult an advisory committee of the type which has advised on similar cases under the insurance scheme. The doctor has the ordinary legal rights to go to the courts on grounds of unlawful action by the Minister or others.

General Comment

Being responsible to Parliament and the nation, the Minister must have ultimate jurisdiction as to the nature and quality of the service provided. But the Act has gone as far as it justifiably could in providing that he should delegate this responsibility to regional and local bodies in which the profession and others are strongly represented.

The Act will be amended, without doubt: the scheme will be bettered and remoulded as experience is gained. But first it has to be begun if there is to be that experience. The Minister is confident that the mass of men and women working in the medical field now, or about to enter it, will join him in beginning it and in constantly improving it.

Minister to Doctor

The Minister's main statement is prefaced by some general comments addressed to the individual doctor who wants to know how participation in the service would affect him personally.

The term "service," he says, is a misnomer if it is held to imply an organised corps. There is no hierarchy of "supervision" or interference with a doctor's professional judgment and clinical practice: "he undertakes to look after patients and is left to do so in his own way and to the best of his clinical ability." Nor is the practitioner "employed": he enters into a contract which in essence is to look after the patient whose care he undertakes—and to be paid for it from public funds, in these cases, instead of by private fee. He is certainly not a civil servant.

The aim will be to set 4000 as the maximum number of patients for a doctor under the scheme, but there is no rigidity in this. Any doctor can also retain private practice.

Compensation and Superannuation

Doctors who participate on the appointed day will establish their claim to their share of the £66 million set aside as compensation for their being unable in future to sell public practices. The Minister is prepared to take the profession's advice as to how this should be equitably distributed. Normally, it will be payable when capital values would otherwise be realised—on retirement or death—with interest in the meantime. But if there is hardship, like some undue debt burden on the practice, it can be paid at once. If a doctor wants, later on, to stop practice for any reason he can draw his compensation at once and do so.

In addition, a superannuation scheme is to be started, the doctor contributing 6% of the payment he receives in the new service (less a percentage for "practice expenses") and the Government 8%. The benefits will include a pension and a lump sum on retirement, a death benefit, and a widow's pension.

Assistants

As before, the engagement of assistants, paid by the doctor, will permit of enlarged lists of potential patients. In addition there will be a system of grants to doctors for the training of young assistants.

Health Centres

As and when health centres are set up, no doctor will be compelled to practise in them. In such health centres the personal relationship (of "my doctor") will be retained. They will be a substitute for the doctor's home surgery, publicly serviced and equipped. Group practice, like present partnerships, will be encouraged in them.

Doctors in the Running of the Service

Doctors are, for the first time, brought on a substantial scale into every main field of administration of the new scheme—regional hospital boards, boards of governors of teaching hospitals, and executive councils. It is a new experiment in bringing the profession itself into the direct administration. In addition there is to be a Central Health Services Council, with a majority of doctors (to advise the Minister on the whole scheme), and a special Statutory Advisory Committee of the Medical Profession. Both can advise without being asked and the Minister has to publish the Council's report (save only where the public interest prohibits).

The Object

The object of the new Act is a simple one. It is to help, by public funds, to ensure that anyone—the highest and the lowest—should be confident of getting all the best that a great profession can give. If the profession rally to it, the greatest health service in the world can come into being. There is no reason whatever why the personal relationship of doctor and patient—and the professional independence of the doctor—should be affected by a switch-over from private fees to public funds.

A scheme of this magnitude is bound to need correcting, amending, as it is found wanting. But, in its conception, it is something of incalculable social value to the great mass of the population, and the medical profession will be the first to want—as they have wanted—something of this kind. For his part, the Minister is concerned mainly to get this great national scheme launched, and to plan on wider, better lines, with the profession directly cooperating in the management of the new service. He asks the profession to help him in launching it next year and in constantly improving it as it goes along. It is a big thing, and he is confident that the profession will join with him, as constructive and often properly critical partners, in getting it under way.

In England Now

A Running Commentary by Peripatetic Correspondents

THE English medical congress is a notably sedate event at which quiet conversations between friends are interrupted from time to time by a formal address whose content is as familiar to listeners as to the speaker. Elsewhere they manage these things better. For example, an advance bulletin heralding a congress in the New Year and in the New World promises that "the social program will be intense." Now in Britain the only concession to sociability is a congress dinner (30s., excluding wines) and, with luck, a reception by the mayor. Not so at next month's meeting. "Among the events is the . . . Fiesta, in which the participants of both sexes will be attired in typical regional costumes; they should therefore not forget to include this costume in their baggage." This plainly sets a sticky problem for the distinguished British representative. If only he were Austrian, or Dutch, or Danish, it would be easy. Perhaps by claiming a grandmother north of the Highland line he could appear in some non-committal tartan without fear of reprisal. If not he will, I suppose, be driven back to the battered bowler and frayed umbrella which seems to have become the *native costume of middle-class males in our region.*

* * *

An old friend, who asks me to dinner when I am well and promptly puts me into one of his hospital beds when I fall ill, is shortly to retire, having reached the age limit for a professor of medicine. He has to deliver a valedictory address to his students, and his subject is to be: "What to Say to the Moribund." Some doctors, he says, have a rule-of-thumb solution for this most delicate of problems: not a word, not a gesture to indicate the approach of death. Such doctors will have nothing to do with the mysteries beyond the veil. The professor himself has as many solutions as he has moribund patients, with this one rule applied to all—to do as he would be done by. One of his patients was an old cancer-phobe doctor with a tumour in the lower abdomen. "Is it that, Professor?" he asked. "Yes, I am afraid it is," came the answer, and the word cancer was never mentioned. It is curious, the professor notes, how seldom hospital patients themselves broach the subject of impending death. Is it that the relation of hospital doctor to hospital patient is seldom tête-à-tête and leisurely?

Looking back, I can remember only one occasion, 40 years ago, when I blurted-out a death sentence. It was murder with a bludgeon. The patient was a middle-aged chemist recently admitted to a private sanatorium whose one and only doctor was about to take a holiday. The doctor said to me as I took over: "So-and-so is a 'gonner.' It is your duty to tell him so." There was still plenty of fight in him when I began. When I had finished a minute later he was down and out. A knock-out blow in the ring could hardly have been more instantaneously effective.

Once I was the recipient instead of the donor of a death sentence. The exceedingly able doctor in charge of me felt obliged to tell me my days were numbered. He did so with infinite tact and well-graduated circumlocution. I smiled to myself, for the point to which he guided me so skilfully was one I had reached long before on my own account. Now he is dead and I am alive and kicking. All of which suggests that silence is golden.

* * *

Patients always say they have never closed an eye all night; their nurses always swear that they have put in the regulation eight hours. The psychiatrist adjudicates according to—well, perhaps according to the laws of chance more than anything else, with some attention to the dictum that if the patient says he has not slept well then at least he has not slept well enough. A night in a tilted armchair in a transatlantic plane is instructive. All night, it seems, one is not sleeping; one hears the engines all the time; one even looks at one's watch like the patients who report the hourly striking of the clock—and suddenly and inexplicably it is Gander, and one has certainly not been *awake* for eight or nine hours. It seems that an interrupted sleep or a light sleep, either of which allows some perception of the surroundings, gives the impression of sleeplessness.

Letters to the Editor

GASTRIC CANCER

SIR,—A whole corpus of statistical legend has gradually grown up around the subject of gastric cancer. There is little or no evidence in support and strong evidence against, but, as the history of medicine shows, facts can be almost powerless against the imaginative appeal of the attractive story. Mr. Shorter (Dec. 6) gives all the main myths with an excellent bibliography in a single paragraph. He tells us that though the total incidence of all forms of cancer is much the same in different communities, gastric cancer has important variations. "The racial incidence varies from 20% of all cancers in Great Britain to about 40% in America"; the preponderance of males is much greater in America: "the highest incidence" is "between the ages of 40 and 60"; gastric cancer is "much commoner in the poor than in the rich."

It is impossible to impugn so many statements in a single letter, but the following table is one of many which could be constructed from official figures to show how similar the incidence of gastric cancer is in comparable populations; and if Mr. Shorter cares to browse more carefully into available death returns, he will see how unwise he has been to rely on the authors whom he cites. The 1939 English and 1940 U.S.A. figures have been chosen as the latest available information undisturbed by war from the particular countries Mr. Shorter has mentioned.

Gastric cancer: male mortality per 100,000

Age-group	*England and Wales* (1939)	*U.S.A.* (1940)
25–35	2·1	2
35–45	10·7	11
45–55	42·8	43
55–65	108	111
65–75	217	199
75–	297	210

These figures demonstrate how readily huge differences in the apparent incidence of gastric cancer can arise if statistics are handled light-heartedly. The incidence over the age of 65 (where diagnosis and death certification is most unreliable) is high compared with the incidence in the younger age-groups where full investigation and operation are probable. Unless care is taken to allow for the exact age and sex distribution of the populations compared, and to consider the effect of varying investigation and autopsy facilities in the older age-groups, the undoubted similarities will be obscured by the dubious differences. Exact figures also show how rarely gastric cancer is the cause of indigestion and how impractical it is to push investigation to the point of diagnostic laparotomy.

GLINICAL IMPRESSIONS OF MALARIA AND LIVER DAMAGE

SIR,—The paper by Professor Maegraith, Dr. Andrews, and Dr. Gall in your issue of Nov. 29 encourages me to describe a group of cases I saw in Siam while a prisoner-of-war.

Two of us were medical officers to a party of 400 men working on the Mergin road from May to August, 1945. Of these, 100 died; and about half of these died in an unusual manner. Their illness began with a continuous fever of about 102°F. After five days they began to hiccup and became deeply jaundiced. After another four days they went into coma. This was not the irritable coma with hypertonia of cerebral malaria but a deep coma with stertorous breathing suggestive of hepatic failure; after every few respirations they would hiccup. After three days in coma they died. At the onset there was complete anorexia. Vomiting was present but was not severe. There was no hæmaturia or tendency to general hæmorrhage. The urine was scanty and coloured by bile pigment—not hæmoglobin. There was some enlargement of the liver and spleen, but of no great degree. At first we thought this was a leptospiral infection, but later some men were evacuated to the hospital camp at Nakon Paton and died in this manner. We heard that the blood slide from all of them showed *Plasmodium falciparum*. It is my feeling that these cases were due a hepatotoxic strain of *P. falciparum*. They did not semble the textbook description of bilious remittent ver, which I did not encounter.

Another camp in Siam, called Hindato, had a higher cidence of cerebral malaria than anywhere else. I ed to wonder whether the local strain of *P. falciparum* s perhaps of an encephalopathic type. We treated ese cases with home-made intravenous quinine. Just der half of them died. Those who recovered invariably d a large bed-sore. Blackwater fever, on the other nd. was sporadic in incidence—which suggested to e that it was due to a variation in reaction by the tient, not by the parasite. We had cases in men ho had never taken quinine. We treated them where ssible with mepacrine tablets crushed up in boiled ater and given intravenously. One man recovered, ough treated with quinine, as quickly as those given epacrine. Only about 1 in 4 of the patients with blackater fever died—usually of superimposed cerebral laria.

We had an occasional case of dysenteric malaria, and y impression was that it was due to the interaction of o diseases. I saw no case of a choleraic. algid. cardiac, purpuric type. I saw 3 cases resembling acute hæmotic anæmia with air-hunger, and a lemon-yellow skin d conjunctivæ, without hæmoglobinuria. Cases presentg with features of an acute abdominal condition re probably due to salt-deficiency cramps, and usually ter an hour the abdominal rigidity had worn off.

London, S.W.3. F. E. DE W. CAYLEY.

GLANDULAR ENLARGEMENT OF UNCERTAIN ORIGIN

SIR,—This report on a case seen in general practice, which an early diagnosis of glandular fever had later be reviewed against an alternative diagnosis of ypical rubella, is prompted by Dr. Royd Jones's ticle (Dec. 6).

The patient, a school-teacher, was an unmarried woman, ged 41. First seen on May 20, she complained of slight alaise for one day, accompanied by a generalised faint pink acular rash. Temp. 99°F, pulse-rate 86 per min. The use of her indisposition was considered to be her tonsils, hich were both covered with exudate. The tonsillar glands ere enlarged and tender. The throat was not sore, however, ither then or on any of the subsequent 12 days on which e tonsillar exudate remained. She felt reasonably well hroughout her illness, except for a certain amount of ckache and malaise on the first 4 days. She was put on ulphamezathine, 2 g. four-hourly.

2nd day.—Increased exudate on tonsils; tonsillar glands arger. Glands in posterior triangle, postauricular and ccipital glands enlarged and tender. Nasopharynx healthy. ars normal; no scalp sepsis. Spleen not palpable Temp. nd pulse-rate normal, and remained so for the rest of illness. ulphamezathine was stopped after 12 g. had been given, eing obviously ineffective.

4th day.—Enlarged tender glands both axillæ and groins. light conjunctival injection. Very marked irritating cough ithout obvious cause: thought to be due to enlarged mediastinal glands. Rash faded. Throat-swab—no diphtheria acilli, Vincent's organisms, or hæmolytic streptococci. Paul-Bunnell test negative White blood-cells 6000 per c.mm. (polymorphs 58%, lymphocytes 28%, monocytes 11%, eosinophils 2%, basophils 1%; about one-third of the lymphocytes were abnormal in type).

5th day.—Spleen palpable, remained so for 5 days. Otherwise no change.

9th day.—Still abundant exudate on tonsils. Glands unchanged. Further throat-swab revealed no pathogenic organisms. Given penicillin lozenges to suck hourly.

12th day.—Throat much cleaner and glands in neck beginning to subside Axillary and inguinal glands unchanged. Repeat differential white-cell count (different laboratory): polymorphs 37%, small lymphocytes 27%, large lymphocytes 12%, monocytes 7%, eosinophils 4%, Türck cells 1%, atypical lymphocytes 2%.

18th day.—Throat clear. Glands in posterior triangle of neck, tonsillar and left axillary glands just palpable.

25th day.—No palpable glands. Patient recovered.

From the 3rd day onwards this seemed to me clinically most likely to be a case of the anginose type of glandular fever. But the negative Paul-Bunnell test rather shook my confidence in the diagnosis, and as an alternative I favoured the possibility of atypical rubella, of which there were several cases in the immediate vicinity. There was, however, also a proved case of glandular fever with a positive Paul-Bunnell test in the neighbourhood at the same time.

I recollect seeing another case, clinically identical with glandular fever, in which there was a history of prolonged contact with a proved case of glandular fever, and in which a negative Paul-Bunnell test left one hard-pressed for a diagnosis.

Great Dunmow, Essex. PETER A. WALFORD.

ORIGIN OF CEREBRAL SURGERY

SIR,—The case mentioned by Major-General Holt (Nov. 1) was described by my late friend, Walter E. Dandy, in Lewis's "Practice of Surgery" (vol. XII, p. 13):

> "During the discussion of Godlee's paper Ferrier reported a case of brain tumor operated upon by Lister some time before Godlee's case. The patient had hemiplegia of the left side, the right eyeball was more prominent than the left and headache was in the right frontal region, the patient being semiconscious at the time. Lister trephined over the right frontal region and the brain protruded so markedly through the defect that exploration was impossible. He introduced his finger into the cortex, ruptured a hydrocephalic ventricle but could feel no tumor. The patient improved during the next few days owing to the evacuation of fluid, but coma again developed and death occurred eight days later. The wound had healed so perfectly that Lister was confident that surgery of the brain was assured. At necropsy it was found that the tip of Lister's finger had missed the tumor by only half an inch. Although unsuccessful by a narrow margin, this case may also be regarded as the beginning of intracranial surgery, but so far as I can learn it has never received recognition."

TREATMENT OF STRANGULATED FEMORAL HERNIA

SIR,—An important clinical syndrome to which insufficient reference is made in surgical textbooks is the strangulated femoral hernia of several days' duration. In these cases the gangrenous portion of bowel has sloughed, and the process has not infrequently extended to abscess formation. The classical clinical picture is modified by this late complication in that all the signs of inflammatory reaction have developed in and around the inguinal swelling. These signs, in addition to the length of history, the presence of intestinal obstruction, and the general condition of the patient, make the diagnosis of the complication strongly probable.

In such a case the orthodox surgical approach is as likely to kill as to cure, since the grave risk of a fatal form of peritonitis is almost unavoidable. There is also the considerable factor of a major operation involving resection in a debilitated and toxic patient. I have for many years been increasingly convinced that an alternative surgical procedure is life-saving and that the end-results are equally satisfactory.

After replacing fluid and salt loss and aspirating the proximal gut, the abdomen is opened by a right or left subumbilical paramedian incision. A lateral anastomosis is then performed by the aseptic method between the distended in-going and the collapsed out-coming segment of the ileum. The inguinal swelling is left untouched. Several days later a fluctuant abscess has formed which is incised and drained. The pus has a fæculent odour and there are usually sloughs which are gently removed at the same time.

No fæcal fistula or persistent sinus has resulted from the incision, and no further operation has been carried out on any case treated in this way. Adequate repair is probably achieved by plugging of the femoral canal with scar tissue. I believe that this method of surgical management in the late strangulated femoral hernia involving intestinal obstruction should be more widely known.

London, E.11.
D. LANG STEVENSON.

STREAKY BLOOD FILMS

SIR,—The observations of Boveri, Waterfield, and Newman, recorded in your issue of Dec. 6, appear to be related to some unexplained observations I made on the bloods of Africans suffering from gambian trypanosomiasis.

In these bloods the plasma albumin-globulin ratio is usually reversed. There is intense rouleaux formation and the blood-sedimentation rate (B.S.R.) is much increased. I do not know if the plasma-fibrinogen is usually altered. If the B.S.R. is performed with whole citrated blood and repeated after remixing one hour later the two results are almost identical. If, however, defibrinated blood is used with or without citrate, the first B.S.R. reading is only slightly less than that of whole blood, but on remixing at the end of one hour both sedimentation and rouleaux formation have entirely disappeared. This occurs at blood temperature and at 0°C.

One part of a 10% solution of suramin to 4 parts of blood is an excellent anticoagulant, and it also prevents rouleaux formation and sedimentation. These properties might be of practical use in hæmatology.

Dorchester. C. HOLLINS.

PROLONGING THE EFFECT OF INJECTED SUBSTANCES

SIR,—Sir Alexander Fleming, F.R.S., discussing the properties of penicillin at the International Conference of Physicians, is reported in your issue of Sept. 13 to have said: "Lately the main objection to the oil-beeswax mixtures—that they solidify on cooling—has been overcome; but prolonged action can equally well be obtained by injecting very large doses of a watery solution."

At the Hamburg meeting of the German pharmacologists on Aug. 23 I showed, on the basis of experiments with R. Kindler, that the effect of morphine injected subcutaneously into dogs (1 mg. per kg. body-weight) could be greatly increased in duration by increasing the dilution of the morphine solution. The implications of this observation for general pharmacology are discussed in an article which is to appear in the *Zeitschrift für Naturforschung.* Sir Alexander Fleming's statement reflects the bearing on clinical medicine of this finding.

Institute of Pharmacology, KLAUS SOEHRING.
University of Hamburg.

INTENSIVE TREATMENT OF KALA-AZAR WITH SODIUM ANTIMONYL TARTRATE

SIR,—I read with considerable interest the article by Dr. Adams and Dr. Seaton (Oct. 18), and noted that the authors were most careful not to make extravagant claims for this treatment. Nevertheless, I have subsequently heard several comments on this paper which suggest that it may have conveyed a wrong impression, and, as there are few today who have had much experience with the antimonyl tartrates in the treatment of kala-azar, some cautionary remarks would not, I feel, be out of place.

I used sodium antimonyl tartrate from 1917 until 1923, almost exclusively, in the treatment of oriental sore and kala-azar. In 1923 I obtained large samples of a variety of pentavalent antimony compounds for trial in kala-azar, and, finding that even the least effective of these gave better results than sodium (or potassium) antimonyl tartrate, we abandoned the latter drug for use among inpatients; but, as we always had between fifty and a hundred outpatients under treatment, we had to continue to use the antimonyl tartrates among these, for several years.

Before the introduction of the treatment by the antimonyl tartrates, kala-azar was a fatal disease; possibly between 5% and 10% of patients recovered spontaneously while under treatment, but there was little evidence that any special treatment was responsible for these recoveries. Therefore, a drug that produced a 75% cure-rate was naturally received with enthusiasm, and the disadvantages and dangers associated with the treatment were accepted as *relatively* unimportant. Actually, they were considerable, and frequently compelled us to modify the prescribed course of injections. The most troublesome by-effects were violent coughing, vomiting, and joint pains. In addition to this there was always a high mortality among patients under treatment. In a series of 139 hospital patients treated by sodium antimonyl tartrate, which I reported in 1924, 14·4% died. This was a lower death-rate than that reported by Knowles in 1920. Pneumonia was a common cause of death. When the pentavalent compounds came into use deaths during treatment became rare and pneumonia was practically unknown.

A variety of strengths of sodium antimonyl tartrate were used, but as no differences in the effects of the various strengths could be detected, a 2% solution became the standard strength. We never attempted to give a concentrated course on the lines adopted by Adams and Seaton, but it seems unlikely that this concentration would diminish the unfavourable by-effects of this drug.

The two advantages claimed for this course are rapidity and cheapness. The latter must be granted, but, if experiments are to be made with concentrating the course, would it not be better to use one of the benign pentavalent drugs such as 'Neostibosan' or sodium stibogluconate? The former has been used in daily (divided) doses of 1·5 g. in the treatment of filariasis.

When the results achieved by Adams and Seaton are critically analysed, they amount to the fact that, of 6 patients, 3 were followed for only a short time and may or may not have been cured; on 1 the treatment had no effect; 1 relapsed but was apparently cured by a second course; and 1 was apparently cured by a single course. It is also of interest that 1 developed pneumonia. The only conclusion that can be drawn from the results in this small series is that it is possible to cure kala-azar with a two-day course of sodium antimonyl tartrate.

I have cured patients with two injections of neostibosan given on consecutive days, but I would not recommend that course.

Finally, I do not think that any extension of the series would be justifiable.

London, W.1. L. EVERARD NAPIER.

Public Health

Future of Public-assistance Institutions

THE National Health Service Act provided for the transfer to the Minister of Health (and for administration by regional hospital boards) of those parts of public-assistance institutions used for hospital purposes, and for the apportionment of premises used partly for hospital and partly for other purposes. Since dual ownership and control might give rise to difficulties provision is being made under the National Assistance Bill for each public-assistance institution to be treated as a single unit, the future ownership and management being determined by its predominant user. There will thus be no apportionment of premises. Responsibility for the care of the sick in institutions remaining with a local authority will, however, rest with the regional board; while the care of the non-sick in institutions vesting in the Minister of Health will rest with the local authority.

In a circular (172/47) the Minister urges local authorities to determine, by negotiation with regional hospital boards, which institutions should be vested in the Minister.

Poliomyelitis

Notifications, which totalled 103 in the previous week, numbered 70 in the week ended Dec. 6. This is the first time since the week ended July 5 that notifications have been below the peak figure for 1938—85 notifications in the week ended Oct. 22. The fall from 103 to 70 maintains the more rapid decline which has been noticeable since the week ended Nov. 15; and if this rate continues notifications should be reaching the normal winter level of 4–5 cases a week by the middle or end of January.

Infectious Disease in England and Wales

WEEK ENDED DEC. 6

Notifications.—Smallpox, 0; scarlet fever, 2027; whooping-cough, 1488; diphtheria, 205; paratyphoid, , typhoid, 0; measles (excluding rubella), 2799; pneumonia (primary or influenzal), 530; cerebrospinal fever, 46; poliomyelitis, 70; polioencephalitis, 6; encephalitis lethargica, 0; dysentery, 93; puerperal pyrexia, 112; ophthalmia neonatorum, 45. No case of *cholera, plague, or typhus was notified during the week.*

Deaths—In 126 great towns there were no deaths from enteric fever or scarlet fever, 1 (0) from measles, 4 (0) from whooping-cough, 3 (1) from diphtheria, 59 (2) from diarrhœa and enteritis under two years, and 19 (3) from influenza. The figures in parentheses are those for London itself

The number of stillbirths notified during the week was 210 (corresponding to a rate of 26 per thousand total births), including 24 in London.

Parliament

FROM THE PRESS GALLERY

Medical Practitioners and Pharmacists Bill

AT the committee stage of this Bill in the House of Commons on Dec 9 Mr. JOHN EDWARDS, parliamentary secretary to the Ministry of Health, moved a series of amendments to clause 3 to include alien doctors, who, although they had not served in His Majesty's Forces, had given valuable service in a civilian medical capacity overseas The Bill as amended was read the third time and passed.

QUESTION TIME

Grants to Industrial Health Research

Mr F J. ERROLL asked the Lord President of the Council what was the total amount of Government grants given in the last four years to the Industrial Health Research Board, the number of reports issued during the same period and what was the future policy for the board —Mr. H MORRISON replied The expenditure of the Medical Research Council on that part of their programme in which they are advised by the board amounted to £161,520 over the last four financial years. During the same period 12 reports on this work were published officially, and 46 other reports as contributions to scientific journals. The policy is to continue the expansion which has already taken place on a considerable scale since the war

Answerable for the Regional Hospital Boards

Colonel M. STODDART SCOTT *asked the Minister of Health if* the Government's decision with regard to Ministers' replies to Parliamentary inquiries about nationalised industries also referred to nationalised hospitals and the specialist and other services administered by regional hospital boards —Mr. A. BEVAN replied. No The Health Ministers will be answerable for these services and therefore for their administration by the local or regional bodies set up for the purpose But it is to be hoped that the proper responsibilities of those bodies will not be diminished by too many inquiries on detailed day to-day matters unless some point of general importance is involved

Analgesia for Mothers

Mr R W SORENSEN asked the Minister to what extent progress was being made in providing analgesia for women in confinement —Mr BEVAN replied The number of cases where it was provided by domiciliary midwives increased from 7262 in 1945 to 20,507 in 1946 Also the number of midwives trained to give it has doubled in the current year I am not yet satisfied with the progress It is substantial but there is still a very large number unable to avail themselves of it

Production of Audiometers

Mr. EDWARD EVANS asked the Minister whether he had arranged for the purchase of a sufficient number of pure tone audiometers for testing purposes in the scheme for the suitable allocation of hearing aids under the National Health Insurance Act —Mr BEVAN replied I am arranging for the production of a new type of pure tone audiometer which can be used after a short and simple training This will be given as may be necessary to the staff of hospitals providing the service

Obituary

ROBERT ALEXANDER FLEMING

M.A., M.D. EDIN., LL.D., F.R.C.P.E.

Dr. R. A. Fleming, the oldest fellow of the Royal College of Physicians of Edinburgh, died on Dec. 6. The son of a Dundee merchant, he was born in 1862, and from Craigmount School he entered the University of Edinburgh where he graduated M.A. in 1884 and M.B. with first-class honours four years later. In 1896 he was awarded a gold medal for his M.D. thesis.

As was the custom at that time, he was pathologist to Edinburgh Royal Infirmary for several years before he was appointed to the staff. He also lectured on the practice of medicine, and he was an examiner for Edinburgh and Aberdeen Universities. As a territorial he served in the war of 1914–18 in the 2nd Scottish General Hospital, and later, with the rank of major, was in charge of the medical division of the 42nd General Hospital at Salonika. He was a member of that select body, the King's Bodyguard for Scotland, the Royal Company of Archers, which he also served as surgeon. He became a fellow of the Royal College of Physicians of Edinburgh in 1899, and in 1928 he was elected president. In the same year the university conferred on him the degree of LL.D. He was also a fellow of the Royal Society of Edinburgh.

But perhaps the duties which gave him most pleasure and interest were his appointment as physician to the two Royal Edinburgh Hospitals for Incurables, which he visited at least once each week, always making a point of speaking to the patients, and his post as medical adviser to the Prison Department for Scotland. In visiting the prisons he showed a deep concern for the welfare and reformation of the prisoners, and for his Morison lecture of 1934 he chose as subject the Mental Element in Crimes and Criminals. Kindness and consideration for others were characteristic of the man, and he earned the affection of all with whom he came in contact. Fond of fishing and shooting, he spent much of his holidays at his shooting-lodge in Perthshire, where he went a few months ago in the hope that in country surroundings his health might improve; and there he died.

Dr Fleming lately celebrated his golden wedding to Eleanor Mary, a daughter of the late Canon W. L Holland, rector at Cornhill-on-Tweed. She survives him with three sons and a daughter.

THE LATE DR. BOLTON

Prof G. Payling Wright writes: In many ways Charles Bolton was fortunate in the unconventionality of his medical training. Long before he began the formal scientific discipline, he had acquired much medical knowledge and skill in observation through his apprenticeship to a general practitioner. Having this practical experience for his background, he was suddenly thrown into the great London medical school which saw the renaissance of physiology in this country With the problems and difficulties of practical clinical medicine he was already familiar; it was hardly surprising, therefore, that his finding in the sciences of physiology and pathology, the solutions to many of his former perplexities, should instil in him a deep urge to follow methodically in the footsteps of the active group of investigators whose steady flow of discoveries had already disclosed so much and held out even higher hopes for the future

The large number of Bolton's contributions to medicine can only be fully appreciated by any one who has gone carefully through the list of his published writings.

While it is difficult to discriminate in value between the three main phases into which his researches fell—the complications of diphtheria, the genesis of peptic ulcers, and the pathology of œdema—it is likely that the last was the most important contribution that he made In his study of this problem he was fortunate in having his friend Starling's researches into lymph formation to guide him. But Bolton had a strongly *independent nature*, and while he fully appreciated the importance of the advances made by Cohnheim and Starling, he was unable to accept in their entirety the applicability of their conclusions to the clinical problem of œdema. For example, in writing of the mechanism by which experimental cardiac embarrassment leads to the formation of œdema, he stated that "the only possible conclusion to which Cohnheim could possibly have come from his experiments was that the venous pressure was high and maintained its height, and this conclusion was wrong only because his method of experiment is not strictly comparable to uncompensated heart disease." With Bolton, the animal experiment was never more than a finger-post; the quest was invariably followed to the bedside of a sick patient. Cohnheim's experiments were *not comparable*, Bolton believed, because they were acute and not chronic in design; so he set himself the task of producing chronic circulatory disorders, and his beautiful experiments on pericardial constriction and partial venous occlusion were the results. From these he concluded that a permanently raised venous pressure was not essential for œdema formation, but that this disorder is "primarily due to impairment or other alterations in the capillary wall"—a view since supported by many later investigators.

Collaborating with Bolton in his investigations was a stimulating experience, for in the laboratory his natural forthrightness suffered none of the inhibitions inseparable from the consulting-room and ward. But however busy he might be with his clinical work, he punctiliously set aside certain afternoons each week when nothing would draw him away from his laboratory. It was this careful arrangement of his time, throughout most of his professional life, that made it possible for him to undertake so many outside activities successfully, yet to maintain an almost unbroken series of original contributions for nearly forty years. He was versatile, too, in his technical skill—his command of experimental methods can be seen in his careful study of the pharmacological actions of an African arrow poison which he made at the request of Ray Lankester. He had unusual skill in animal surgery—the deftness of his technique contrasting strangely with his large and seemingly ungainly fingers. But in spite of his exceptional facility in such operative procedures, he always subordinated his methods to the research in view, and turned to chemical, immunological, and other techniques as the occasion required.

Bolton was a man of most kindly nature, and the open frankness of his character tended to evoke the best from all who came closely into contact with him. Away from the ward and laboratory, his main interests lay in the open air. He spent many of his holidays fishing, for he was a keen angler. His boyhood in Yorkshire, too, had left him with a deep interest in natural history and the wild life of animals, and as with so many medical men this interest had reinforced his natural gift for observation. Perhaps no higher tribute could be paid his qualities than that he had the robustness of frame, intellect, and character that is typical of the people of the countryside from which he sprang.

Births, Marriages, and Deaths

BIRTHS

Aronson.—On Dec. 6, in London, the wife of Dr. Robert Aronson—a son.

Freeman.—On Dec. 8, in London, the wife of Dr. V. Freeman—a son

Harrington.—On Dec. 7, at Church Crookham, Hants, the wife of Dr. A. W. Harrington—a daughter.

Higgitt.—On Dec. 2, in London, the wife of Dr. A. C. Higgitt—a son.

Lennie.—On Dec. 9, at Bath, the wife of Dr. A. B. Lennie—a daughter.

Street.—On Dec. 3, the wife of Dr. W. J. Street—a son.

MARRIAGES

Lane Roberts—Ford.—On Nov. 29, at Abingdon, Berks, Peter Anthony Lane Roberts, B.M., to Irina Ford.

Russell—Eyre.—On Dec. 6, at Carlton Colville, Michael H. Russell, M.B., to Pamela Eyre.

Whitehouse—Barker.—On Dec. 6, in London, John Whitehouse, M.R.C.S., R.A.F.V.R., to Anne Barker.

DEATHS

Adam.—On Dec. 10, in London, John Ewing Adam, M.D. Glasg., F.R.C.S.E., D.P.H., aged 78.

Hegarty.—On Dec. 8, in London, Patrick Nicholas Hegarty, L.R.C.P.I.

Marriott.—On Dec. 10, in London, William Marriott, M.R.C.S.

Masson.—On Dec. 7, in London, Hamish Falconer Masson, M.A., M.B. Edin., F.R.C.S.E., aged 45.

Perrott.—On Dec. 10, at Ilford, Essex, George Francis Donaldson Perrott, M.A. Camb., M.R.C.S.

Smith.—On Dec. 6, at Chipping Norton, Oxon, Thomas St. Clair Smith, B.A., M.B. Camb., aged 71.

Stone.—On Dec. 9, at Dorking, William Gream Stone, M.A., D.M. Oxfd, F.R.C.S., aged 81.

Notes and News

FIRST MAKER OF CHLOROFORM

The centenary of the discovery of chloroform anæsthesia by James Young Simpson was fitly celebrated by the University of Edinburgh a few weeks ago. Another pioneer who deserves to participate in the credit accorded to the memory of Simpson has been remembered in a little book[1] which has just appeared.

Ether was known for three centuries before it was used as an anæsthetic, and the substance chloroform antedated the anæsthetic chloroform by seventeen years. Almost simultaneously, and quite independently, chloroform was prepared by Liebig in Germany, Soubeiran in France, and Guthrie in America, in the year 1831. A priority of several months over the other two chemists is usually accorded to Dr. Samuel Guthrie, of Sacket's Harbour on Lake Ontario.

Guthrie's grandfather, James Guthrie, a Scot and a descendant of the martyr covenanter of that name, landed at Boston, and had a son and a grandson, each of whom practised medicine in Massachusetts. The grandson did not confine his attention to medicine. In the early days of his practice he set up a gunpowder mill, and there he invented the percussion cap for firearms, which soon replaced the old-fashioned and clumsy method of priming. Not content with one factory, Samuel Guthrie also conducted a distillery, and early in 1831 he mixed three pounds of chloride of lime with two gallons of whisky, and then boiled and distilled it, thus obtaining chloroform, although it was not called chloroform until several years later. Taken internally, this new liquid "appeared to be singularly grateful both to the palate and stomach, producing promptly a lively flow of animal spirits, and consequent loquacity, and leaving, after its operation, little of that depression consequent to the use of ardent spirits. For drinking, it required an equal bulk of water." Such was the report contributed by Guthrie to the *American Journal of Science and Arts*, 1831–32, and to it was appended an editorial note by Professor Silliman, expressing the hope that further experiment would show the new substance to be of value in medicine as a remedy, and not merely as a stimulant. "He would be no benefactor to his species," continued the editor, "who should add a new attraction to intoxicating spirit."

Nevertheless the liquid became known as "Guthrie's sweet whiskey"; though the discoverer declined to go to New York, where he could have made a fortune by exploiting the new-found intoxicant. He is said to have noticed that the fumes had a soporific effect upon the cats in his wood-yard, but this observation was not followed to its logical conclusion by any experiment and thus chloroform continued to be used internally for its stimulant effect in asthma and other ills, until Simpson revealed its anæsthetic properties in 1847.

Guthrie died in 1848, at the age of 66, in the home of his daughter Cynthia. He was long remembered for his kindness and generosity, and in 1888 an inscription setting forth his discoveries was placed upon a huge boulder in Washington Park, Chicago, a tribute from the Chicago Medical Society. His home, his firearms, his still, his factory, and his memorial boulder are among the illustrations of this book, but unfortunately there is no portrait of Guthrie himself: apparently his daguerreotype was never taken.

THORACOLUMBAR SPLANCHNICECTOMY

At a meeting of the Liverpool Medical Institution on Nov. 27, Mr. F. E. Stock said that none of the various incisions described for the operation of thoracolumbar sympathectomy had given complete satisfaction; for while exposure of the *lumbar sympathetic chain* was satisfactory, the view of the dorsal sympathetic chain was very poor. Fey had described an incision for the approach to the upper pole of the kidney which was made far more anteriorly than the standard kidney incisions; and after using this incision several times it was apparent that the extension of it would give a very satisfactory exposure of the lower dorsal sympathetic chain.

The incision commences just behind the posterior axillary line and passes downwards to a point just in front of the anterior superior spine. For convenience it can be made in two stages, but this is not essential. The posterior half of the incision is deepened on to the rib and the periosteum incised. The periosteum is then displaced with an elevator from the upper half of the rib and upper border. Unless the rib is to be removed (which is unnecessary) the periosteum should not be stripped any farther from the back and lower edges. On depressing the rib, fibres of the diaphragm are seen passing upwards and forwards from the front 2–3 cm., and these are divided with a knife. The anterior part of the wound is then deepened by separating the fibres of external oblique which run in the line of the wound, and dividing the fibres of internal oblique and transversus abdominis. The rib and posterior muscles are gently retracted, the kidney in its fascial capsule is displaced forwards, and the great splanchnic nerve is immediately seen piercing the crus of the diaphragm. The next step is the division of the diaphragm, the free edge of which can be seen at this stage crossing the upper part of the wound. A finger can be inserted above the diaphragm and the pleura separated from it by gentle pressure. The diaphragm is then divided with scissors approximately 1 cm. from its origin as far back as the crus where it is pierced by the splanchnic nerve. The thoracic part of the operation then commences, the pleura being displaced from the posterior chest wall by blunt dissection, as far as possible in an extrafascial plane. This extrafascial plane can be found easily by commencing dissection at the point where the great splanchnic nerve pierces the diaphragm, but it is not always easy to remain in the plane and on several occasions the pleura has been opened. The wound is closed by re-suturing the diaphragm and closing in layers. An encircling suture is not placed around the eleventh rib as this was found to produce a pressure neuritis of the eleventh nerve.

INSTITUTE OF SOCIAL PSYCHIATRY

About fifty psychiatrists and psychiatric social workers attended a meeting of this new institute held on Nov. 15, to exchange views and experiences in running therapeutic social clubs. Dr. Noel Harris, who was in the chair, said that, from his experience, many patients had benefited from the work of these clubs. Dr. J. Bierer outlined the basic principles of social psychotherapy, and Dr. M. B. Brody asked members taking part in the discussion to deal with the following points: should social therapy be combined with group therapy; should the clubs be self-supporting—or should they be supported by hospitals or other agencies; should discharged patients from mental hospitals and patients attending outpatient departments attend the same club; should one mix people with different diagnoses with people of different intelligence and social standard; should elections often be held, and should the patients run clubs completely independently.

The following reported on the work of their clubs: Dr. Somerville (West Ham Hospital), Dr. de Maré (St. George's), Dr. Lindsay (Middlesex Colony), Dr. Blair (St. Mary's and St. Bernard's), Miss Millar (Glasgow), Dr. Fysh (Roffey Park), Dr. Sandison (Warlingham), Dr. Scott (East Ham Hospital), Miss Butcher (Phœnix Club, Kingsway), Dr. Smith (Southend Hospital), Dr. Aaron, Dr. Bevan Jones, and Miss Thompson (Runwell Hospital).

The discussion will be summarised at a further meeting to be held at Seymour Hall, Seymour Place, London, W.1, on Wednesday, Jan. 14, at 2 P.M., when the speakers will include Dr. E. B. Strauss, Dr. Bierer, Dr Donald Blair, Dr Harris, Dr. Doris Odlum, Dr. Maxwell Jones, and Dr. Brody. Further details may be had from the Social Therapy Centre, 7, Fellows Road, N.W.3.

"THE STORY OF A SCOTTISH VOLUNTARY HOSPITAL"

"The Gentlemen dined together, drank many loyal and patriotic Toasts; and passed the Evening with cordial and rational festivity." This glimpse of opening day at the Northern Infirmary, Inverness, published in the press in Edinburgh and London 133 years ago, is typical of the intimate details which Dr. T C Mackenzie has woven into a fascinating narrative.[1] Careful research has yielded a wealth of material, interesting not only to the medical historian but also to sociologist and economist alike. In 1807 "½ year's wages to Matron" amounted to £5, while the gardener received £7 10s A generation which so readily takes for granted the special hospital services to deal with mental diseases, infectious diseases, and tuberculosis receives a salutary reminder of the courageous efforts of pioneers who grappled with these problems long before local authorities and Ministries could be roused to a sense of responsibility. Reference is made to the increasingly important part played by the infirmary in the work of the Highlands and Islands (Medical Service) Board. This is a subject of special interest to readers on both sides of the Border, for there can be no doubt that the development of "H. and I." has received special attention from the architects of the National Health Service.

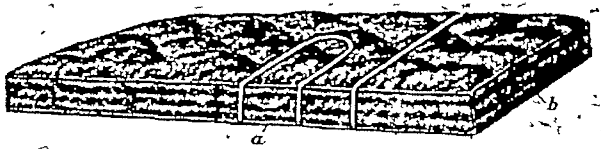
MEDICAL WAR RELIEF FUND

During the past year this fund has made forty-nine awards, to the value of about £11,000; and the total of all awards since the inauguration of the fund is nearly £62,000. As in the previous year, most of the applications came from ex-Service medical officers who needed temporary assistance; but the fund has continued to provide for widows and children of doctors who lost their lives in the war, and a substantial sum was voted to defray the cost of the journey to Switzerland of three parties of children of doctors killed or incapacitated in the war. Dr. C. L Batteson has succeeded Dr. J. W. Bone as treasurer. As already announced (*Lancet*, Nov. 15, p. 743), further contributions are not being sought.

COMMODE BEDSTEAD

Messrs. Siddall and Hilton, of Sowerby Bridge, Yorkshire, write describing a bedstead designed to make easier the use of the bedpan.

This bedstead has a head and back rest, adjustable by means of a handle at the foot end. In the centre of the mesh is an opening strengthened with 1¼ × ¼ in. flat iron, under which a commode can be placed, or on which a bedpan can rest.



Mattress showing (*a*) loose piece which draws out, and (*b*) hinged piece.

The mattress is hinged to fit the adjustable head and back rest. The portion of the mattress over the centre piece is separate and can be drawn out by means of the loop attached (see figure).

The bedstead could be designed to fit the type of commode or bedpan in use in any hospital, and could also be adapted as a cot bedstead.

ACCIDENTS IN THE HOME

At the congress of the Royal Society for the Prevention of Accidents, in Brighton last October, Dr. V. Freeman spoke on Accident Prevention in Relation to Preventive Medicine. His address has now been reproduced as a pamphlet, which is obtainable, price 2*s.* 6*d.*, from the society, 52, Grosvenor Gardens, London, S W.1.

University of Cambridge

On Dec. 6 the degrees of M.B., B.CHIR. were conferred in absence on G. A. Bracewell. During November the title of the degrees of M.B., B.CHIR. was conferred on L. A. Farquharson, J. K. Goodacre, G. F. Jacob, I. Kane, P. D. Kilner, R. M. Licence.

The Raymond Horton-Smith prize has been awarded to Dr. M. G. P. Stoker for his thesis on a laboratory investigation of the rickettsial diseases of India.

University of Leeds

Mr. C. R. Morris, headmaster of King Edward's School, Birmingham, has been appointed vice-chancellor of the university in succession to Mr. Mouat Jones, who retires at the end of this session.

Royal College of Physicians of Edinburgh

At a meeting of the college held on Dec. 4, Dr. W. D. D. Small was elected president, and Dr. R. Cranston Low, Dr. L. S. P. Davidson, Dr. J. D. S. Cameron, Dr. H. L. Wallace, Dr. I. G. W. Hill, and Sir David Henderson were elected councillors for the ensuing year. Sir David Henderson was nominated vice-president.

Royal College of Surgeons of England

At a meeting of the council of the college held on Dec. 11, with Sir Alfred Webb-Johnson, the president, in the chair, the following were elected to the fellowship in dental surgery:

H. Chapman, L. C. Attkins, W. B. Grandison, Bowdler Henry, H. H. Stones, R. Weaver, C. W. Roberts, H. G. Watkin, A. G. Allen, J. F. Pilbeam, Eleanor M. Knowles, G. H. Leatherman, G. L. Roberts, R. Cocker, P. J. Stoy, B. W. Fickling, E. L. Sheridan.

Diplomas of fellowship were granted to the following:

W. A. D. Drummond, D. D. Cranna, J. R. St. G. Stead, H. A. Pearce, N. E. James, B. S. S. Acharya, Isaac Jacobson, C. M. Squire, A. D. Bateman, R. W. Gunderson, J. N. M. Parry, G. H. A. Simmons, W. W. Wilson, N. L. Crabtree, J. C. A. Innes, A. J. S. Bell Tawse, R. C. Fuller, W. McC. Scott, H. D. S. Vellacott, R. P. M. Miles, B. H. Price, B. C. Rowlands, H. P. Guerrier, D. N. Fuller, H. O. Jones, B. W. Wells, R. C. Connolly, M. H. Wostenholm, G. A. Barclay, J. F. North, R. P. Warren, J. F. R. Bentley, J. F. N. Ward-McQuaid, W. E. S. Bain, J. R. Thompson, S. M. Chris, S. R. Mawson, P. P. Rickham, John Fry, F. I. Tovey, Ibrahim Higazi, F. V. Stonham, C. D. Clark, M. T. Greig, L. N. Bartholomeusz, J. R. Grimoldby, Jeremiah Burke, K. B. Burnside, N. C. Hughes, A. C. R. Sharp, R. E. Gibbins, K. N. McNamara, H. M. J. Windsor, K. R. Archer, J. A. Key, R. F. Lowe, E. M. Nanson, D. P. Sapsford, P. R. H. Slade, A. W. Sutherland, R. C. Willis, Sita Achaya, J. R. Addison, David Aiken, T. J. Butler, J. P. Fleming, D. McD. Kenny, K. N. Morris, Bishnupada Mukopadhaya, Jean M. Sandel, Subrata Banerjee, A. A. Brown, R. P. Jepson, Martin Laird, T. F. Miller, Ivan Barnat, Allan Hulme, L. W. Cox, K. N. Dastur, A. W. Fowler, Ian Macnab, J. B. Parikh, A. E. Carter, F. G. Westgate.

Diplomas of membership were granted to R. G. Donaldson (Westminster), B. C. Luker (St. Thomas's), and G. G. Parsons (St. Thomas's), and diplomas in child health, jointly with the Royal College of Physicians, to M. B. Gamat and A. D. M. Jackson.

Royal College of Surgeons in Ireland

On Dec. 12 the fellowship was conferred on Dr. John Bunting.

The Scottish National Blood Transfusion Association

Prof. D. F. Cappell has been appointed chairman of the technical committee of the association in succession to the late Sir John Fraser.

British Postgraduate Medical Federation

The federation has awarded postgraduate travelling fellowships for 1947 to Dr. S. C. Gold, (dermatology, Switzerland and U.S.A.), Dr. A. Hargreaves (dermatology, Switzerland and U.S.A.), Mr. R. Shackman (surgery, U.S.A.), and Dr. D. B. Taylor (pharmacology, U.S.A.)

A Medical Film Unit

John Curthoys Productions have formed a medical film unit under the direction of Dr. Brian Stanford. A programme of short films and filmstrips dealing with medical subjects of interest to industrial workers, nurses, and others, has been drawn up. It is also hoped to produce a series of documentaries. The unit is willing to put its equipment and staff at the disposal of hospitals on a non-profit-making basis, when the material is required for medical instruction or research purposes.

Medical Short-service Commissions for Women

Short-service commissions are being offered to women in the medical and dental branches of the Air Force.

The commissions will be for four years' active list and four years' reserve service, with a gratuity of £600 for medical officers and £500 for dental officers payable after satisfactorily completing service on the active list. The successful applicants will be granted Air Force rank, and their rates of pay, promotion, and conditions of service will be the same as for male medical and dental officers. The upper age-limit for medical candidates is normally 30, but those who are not 32 on the date of ap
There is no age-limit for applicants to
tion forms may be had from the
Services, Air Ministry, Awdry House,

Award to Ministries

On behalf of the Ministries of Health and Food, Sir Wilson Jameson, chief medical officer of the Ministry of Health, received in October a Lasker award from the American Public Health Association. The award, which takes the form of a statuette of the "Winged Victory of Samothrace," is on view at the Ministry of Health. This is the first time that the award has been given to a foreign country; and the citation, commending "the unprecedented programme of food distribution in Great Britain, with resulting improvement in the health of the people," names in particular Lord Woolton, Sir Jack Drummond, F.R.S., Sir Wilson Jameson, and Sir John Boyd Orr, F.R.S.

Tuberculosis Association

Dr. F. R. G. Heaf has been elected president of this association.

St. John's Hospital, London

An appointment system for all patients will begin at this hospital for diseases of the skin on Jan. 1.

Women Dental Assistants

Guy's Hospital dental school has arranged a six-month course to train a limited number of women as dental surgery assistants. Applicants must produce certificates of proficiency in first-aid and home nursing and in secretarial work.

Grants for Old People's Homes

Since it was established in August, the National Corporation for the Care of Old People has made grants of over £133,000 towards the cost of homes and other welfare schemes for old people. Of this sum, £64,000 has come from the Lord Mayor's National Air Raid Distress Fund.

Penicillin Shortage in the United States

The United States, says B.U.P., is suffering a shortage of penicillin, which is described by Dr. Henry Welch, of the penicillin division of the Food and Drug Administration, as uncomfortable rather than serious. The shortage is ascribed to wider application, to use in larger doses, to employment in diseases of cattle, and to exports of the drug.

Ophthalmological Society of the United Kingdom

The annual congress of the society will be held at 1, Wimpole Street, London, W.1, on April 8, 9, and 10, 1948, when Dr. Macdonald Critchley, Prof. Henry Cohen, and Mr. J. H. Doggart will open a discussion on Subjective Disorders of Vision. Prof. Marc Amsler, of Zurich, will deliver the Bowman lecture. *Further information may be had from the hon. secretary of the society, 45, Lincoln's-Inn Fields, W.C.2.*

North-East Metropolitan Region

The Representative Psychiatric Committee of the North-East Metropolitan Area which was set up last June consists of elected representatives of the medical staffs of the mental hospitals, mental-deficiency institutions, and psychiatric departments of the teaching and non-teaching general hospitals in the area. Its terms of reference are: "to consider and to concern itself with every aspect of the psychiatric services in the region," and its chairman is Dr. Henry Wilson.

Grants for Distinguished Visitors

The British Council has a small fund from which a few grants can be made to permit the attendance of foreign scientists at national or international conferences or meetings held in the United Kingdom. The grants cover subsistence or part-subsistence in the United Kingdom during the conference, and fares are not included. Applications for grants for 1948–49, which must be made by the conveners of the conference, should be sent by Jan. 31 to the administrator of the science group of the council, 3 Hanover Street, London, W.1.

Canadian Red Cross Memorial Hospital, Taplow

Mr. Ralph Marnham, director of the department of surgery, presided over an At Home for local doctors held at this hospital on Dec. 6. *Sir Francis Fraser spoke on* Postgraduate Medical Education at a Hospital Centre, and the wards and departments of the hospital were opened to visitors. Dr. E. G. L. Bywaters, director of the special unit for juvenile rheumatism, Dr. G. D. Hadley, director of the department of medicine, Dr. L. E. Glynn, director of the department of pathology, and other members of the medical and surgical staff of the hospital were present.

VISCERAL PAIN*

HENRY COHEN
M.D. Lpool, F.R.C.P
OF MEDICINE IN THE UNIVERSITY OF LIVERPOOL

dinal paradoxes of visceral pain spring from established facts: first, that whilst pain is onest symptom of visceral disease, organs e stomach or heart when subjected to gross tting, crushing, or burning—appear to be ; secondly, that pain arising from visceral y be located at a distance from the affected in the left arm in heart disease or the testis isease. Attempts to elucidate the enigma of in have led to investigations which fall into s: (1) the nature of the adequate stimulus; e site of its action; (3) the distribution of pain nerve-endings in the viscera; (4) the peripheral and central nervous pathways which lead from viscus to sensorium; and (5) the "mechanisms," both physical and psychological, involved in the *reference* or *localisation* of pain.

In my Lettsomian lectures for 1944 (Cohen 1948) I have reviewed the data on these five aspects of visceral pain, traced the history of current hypotheses, and critically assessed their shortcomings. My more limited purpose here is to discuss how the intensity and localisation of visceral pain are affected by modifying the sensation of skin and deep somatic tissues.

The earliest observations in this field were recorded by Lemaire (1926). In four patients he relieved the pain of gastric ulcer and other intra-abdominal lesions by local anæsthetisation of the abdominal wall. His observations were confirmed and extended by Weiss and Davis (1928), Morley (1931), Theobald (1941), and others. These results, in the main strikingly uniform, leave no doubt that pain arising from viscera can be abolished, diminished, or differently located when the nerves of those somatic segments corresponding to the visceral nerve-supply are anæsthetised.

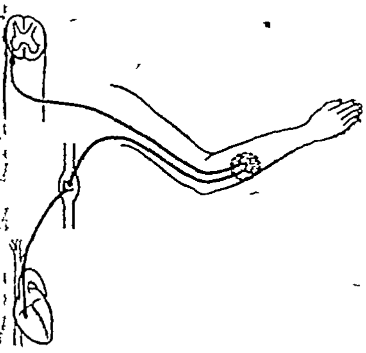

Fig. 1—Penfield's (1925) explanation of reference of anginal pain.

To explain the effects of local anæsthesia and the somatic reference of visceral pain, Penfield (1925) and Davis and Pollock (1932) have suggested that the impulses arising from a viscus cause pain by inducing peripheral changes (vascular or metabolic) which stimulate the sensory nerve-endings in the skin and deeper tissues, and that pain is then transmitted by the usual pathways (fig. 1). That this hypothesis is untenable is suggested by cases published by Wallace Jones and myself (1943). Both patients had had the left arm amputated and suffered from a phantom (figs. 2 and 3). Both, when they later developed angina, located their pain to the phantom. Such reference clearly excludes stimulation of a peripheral nerve-ending, by any mechanism, from playing a significant rôle in the genesis of visceral pain. Moreover, in both these patients anæsthetisation of the brachial plexus, care being taken to ensure that the sympathetic ganglia were unaffected, led to abolition of the arm component of angina in mild attacks, *and its lessening and later appearance in severe attacks* (fig. 4). The second patient had a "pin-head" neuroma at the site marked x (fig. 3), pressure on which caused anginal pain. Anæsthetisation of the neuroma abolished the arm component of the angina on mild effort. The evidence is now overwhelming that interruption of nerve paths between the periphery and the central nervous system in those somatic segments which are homologous with those of the diseased viscus abolishes or diminishes the pain or modifies the time of its appearance.

EFFECTS OF INCREASED SENSITIVITY

But the contrary influence of *increased* sensitivity of somatic tissues on visceral pain also has to be considered. *It is* within the experience of all clinicians that constriction of the left arm with a sphygmomanometer band may excite an anginal attack, but the possibility of the cause lying in reflex coronary vasoconstriction cannot here be excluded with certainty. Stronger evidence is afforded by many cases, of which the following is *typical.*

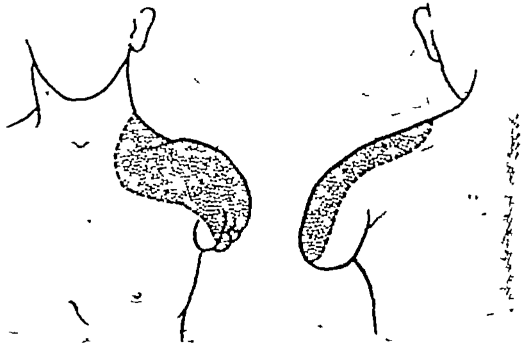

Fig. 2—Area of anæsthesia produced by left brachial-plexus block in patient whose left arm had been amputated.

> A patient with three years' history of effort angina referred his pain to the substernal region. He fractured his left elbow, which when fixed in plaster was free from *spontaneous* pain; but for several weeks after the injury walking brought on pain in the damaged elbow, followed by substernal oppression and a sensation of constriction of the chest.

These clinical observations led to a trial of the effects of experimentally induced hyperæsthesia in superficial and deep somatic tissues on visceral pain. Four patients with effort angina were blistered over an area of 4 sq. in. with a vesicant plaster on the inner side of the right elbow or the right mammary region, where they had not previously experienced pain (fig. 5*a*). When their angina was excited by exertion, all complained early of intensification of pain in the blistered area. In three of these patients 2 ml. of 5% saline was injected into the back muscles 2 in. to the right of the 5th dorsal spine (*fig. 5b*); this gave rise to a diffuse deep-seated pain

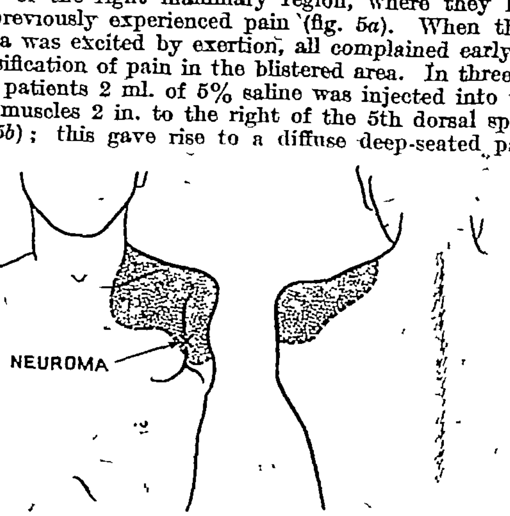

Fig. 3—Position of neuroma in patient whose left arm had been amputated.

---

* A paper read at the International Conference of Physicians, London, on Sept. 12, 1947.

with vague boundaries. Two hours later, when the pain so induced had passed, exertion caused its reappearance, though no pain had in previous anginal attacks been felt in this area. The patients chosen for these clinical experiments were intelligent and coöperative, and I exclude unconscious suggestion on my part from playing any part in the results.

DISCUSSION

It is evident that the blocking of peripheral pathways diminishes, whereas the sensitisation of somatic tissues increases, the ease with which pain of visceral origin is excited. What is the implication of these findings on the postulated mechanism for visceral pain? Clearly the older theories, and the more recent suggestions of facilitation by convergence (Ruch 1947), must be abandoned. Two hypotheses remain to be considered: (1) that visceral stimuli may lower the central threshold to peripheral stimuli (as in the classical Ross-Mackenzie hypothesis), or peripheral stimuli may lower the central threshold to visceral impulses; and (2) that the peripheral stimuli augment those from the viscera. Both Theobald (1941) and Jones (1943) have suggested that a principle of summation of stimuli may be involved in visceral pain, but neither has faced the inevitable corollary which I suggest must be postulated if we are to present a consistent hypothesis. This is that from the endings of all pain nerves, visceral and somatic, there arises normally a constant regular stream of subliminal impulses which pass to the central nervous system. It is true that no neurophysiologist has produced evidence supporting this inference, but none has as yet applied himself to the problem. Sarah Tower (1943) has, however, observed spontaneous and rhythmic discharges in pain fibres and terminals, of 1–8 a second, sometimes for hours. If this be accepted as normal, many hitherto irreconcilable observations on visceral pain can be reasonably explained. Normally these impulses are subliminal; they do not cause pain unless disease lowers the threshold. This raises the question of whether there is an organic peripheral component of the pains which the hypersensitive neurotic feels "all over the body." Pain impulses from a viscus which are augmented in intensity will pass the threshold only if, whether alone or supplemented by those impulses normally arising from homosegmental somatic structures, they exceed the threshold value. This may be expressed symbolically thus:

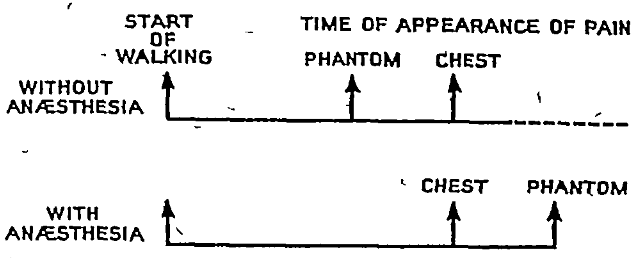

Fig. 4—Relative times of appearance of pain in chest and phantom limb before and after brachial-plexus block.

Let K=threshold for pain, A=normal stream of impulses from somatic tissues, and B=normal stream of impulses from homosegmental viscera.

Then A+B is normally less than K; but K may be exceeded if (1) A is increased, as in pressure on neuroma of amputation scar; (2) B is increased, as in cardiac ischæmia; or (3) A and B are increased, as in the concurrence of cardiac ischæmia and subdeltoid bursitis.

Almost constantly pain of visceral origin is referred to an area which shares with the viscus a common segmental innervation. This homologous segmental reference of visceral pain, first suggested by Martyn (1864) and profitably used by Head (1893) in mapping out the segmental nerve-supply to the viscera, was beautifully demonstrated by Lewis and Kellgren (1939), who emphasised the artificiality of the supposed distinction between visceral and somatic pain. Since the metamere is the phylogenetic unit of the organism, and since the arrangement of pain fibres in cord, brain-stem, and thalamus is segmental, it is highly probable that pain impulses arising from the same segment will reach a functionally related area of the sensorium, and, when *integrated with the cortical pattern of the body image* by neural mechanisms at present largely unknown, will *be localised selectively in that segment*. There is now considerable evidence showing that with repeated stimulation such localisation becomes more precise (Wolf and Wolff 1943), thus suggesting that there is an inborn faculty for a vague segmental localisation of deep and visceral pain (else why the fairly constant localisation of referred pain in angina and biliary colic?) which is amenable to learning by experience.

The explanation of the effects of local anæsthesia and hyperæsthesia is, on the hypothesis here presented, clear. If, on the one hand, the normal impulses streaming up the *somatic-pain nerves contribute significantly to* the sum of pain impulses necessary to pass the threshold, nerve block will abolish the pain; if, on the other hand, the impulses arising from the viscus are above threshold value, the block may diminish the intensity of the pain or alter its maximal site or course of development, but will not abolish it.

This hypothesis has the additional merit of explaining the more frequent failure of subcutaneous nerve block to lessen visceral pain, as contrasted with segmental nerve block. "Without hypothesis," wrote Charles Darwin, "there can be no useful observation." The hypothesis here presented will be supported or discarded when evidence is forthcoming from the neurophysiologist on the validity of the assumption that normally there is a constant centripetal stream of subliminal impulses from the nerve-endings for pain in all tissues. On him *rests the burden of proof*.

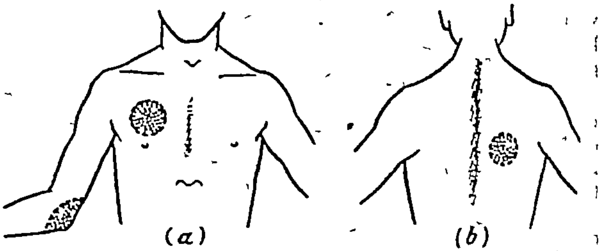

Fig. 5—Areas of experimental hyperæsthesia: (a) by blistering; (b) by injection of hypertonic saline.

SUMMARY

Referred pain of visceral origin can be abolished or diminished, *or its location* may be changed by anæsthesia of homosegmental areas.

It can also be produced, increased, or moved by hyperæsthesia of homosegmental areas.

The explanation of these two *facts* seems to be that there is a constant stream of subliminal impulses from visceral and somatic nerve-endings to the central nervous system.

Normally the sum of such visceral and somatic impulses is subliminal. The threshold value is exceeded, and pain is caused, only by the abnormal increase of either one or both of these two kinds of impulse.

A COMPREHENSIVE STUDENT-HEALTH SERVICE

A. H. MACKLIN
O.B.E., M.C., M.D. Manc.
PHYSICIAN TO THE STUDENT-HEALTH SERVICE, UNIVERSITY OF ABERDEEN

THERE should, in my view, be a full student-health service in every university. Complete health examinations on entry and in subsequent years are not enough; the service should include care of the student when he is sick or needs medical attention of any sort, and, based on these two, a careful inquiry into the factors which affect mental and physical health in this particular age and occupational group.

The students are likely to be more interested in, and to make fuller use of, a service which looks after their troubles and illnesses and, to their way of thinking, has a practical value than one which they may rightly or wrongly suspect of using them as subjects of a statistical inquiry. Without such a service it is difficult to see where accurate information about morbidity, necessary for the assessment of the health and sickness of any group, is to come from.

It is when students are sick and seeking help in trouble that one gets the best insight into their background. In some cases it is the only time when one will get to know anything at all of the more intimate affairs which can have such an important bearing on their mental and physical make-up. I have found that replies to stereotyped questionaries, particularly written ones, are often inaccurate and misleading. A glaring example of this is the replies made to the question: "What games do you play and what form of exercise do you take?" A student will fill in rugby, tennis, rowing, hiking, swimming, squash, badminton, cricket, country dancing, and hill climbing, when what he means is that he has done each of these things once and, since coming to the university, has taken practically no physical exercise at all.

If the student cannot be relied on to answer such simple questions as these accurately, still less valuable will be his replies to more intimate inquiries. In the ordinary way of examination it is very hard to get "inside" a student or to find out much of what constitutes his social and environmental background. This may apply more to the northern Scotsman with whom I have had to deal, but with any group of students it is important to ensure that information given on what are often delicate matters is truly representative before reducing it to figures. As a means to obtaining really valuable information, the doctor-patient relationship should be developed rather than the impersonal stereotyped questionnaire.

It is very important that the physician in charge of the student service should have an absorbing interest in and liking for his work. A long series of routine examinations is apt to become very tiring, and indeed boring, to the detriment of the standard of work. It will prove much more interesting if the day is enlivened with the care and treatment of sick students, and the health examination will mean a great deal more if it is to be the basis of possible further personal care. The physician should be able to feel that he is in a position to carry out, from start to finish, the very highest standard of medical work. This surely is a sine qua non of a university service, and it will not be achieved if the service is broken or disjointed, or the physician's interest is subjected to the strains of a too limited routine.

THE ABERDEEN SCHEME

Aberdeen University and the Aberdeen Royal Infirmary came together to make the student-health service a combined undertaking. The physician in charge is expected to deal with the nurses and residents of the hospital in the same comprehensive way as he does with university students. To regularise the position the holder of the appointment has been appointed to the staff as assistant physician in charge of the nurses' health service and has charge of a flat of small wards totalling 20 beds. The flat was designed primarily for the use of sick nurses, but students, both male and female, can be admitted if there is room. The appointment is useful in that it enables the physician to retain the care of students and nurses requiring hospital treatment or investigation, and puts him in closer touch with other members of the hospital staff, on whom he can call as required, than would otherwise be the case.

The retention of the personal care of the student throughout the whole period of his illness constitutes an important element of the service. To hand him over to some other person or to an institution when the need for contact is greatest would surely infringe the principle, so strongly emphasised in social medicine, of dealing with the individual and the group, in health and in sickness, as a whole being and a whole group.

The accommodation in the University buildings consisted at first of two rooms, but this is now being increased to four:

(1) Consulting and examination room.
(2) Treatment room and laboratory.
(3) Office.
(4) Reception and waiting room.

This must be regarded as a minimal requirement.

The day's routine is generally as follows:

I go at 9 A.M. to the Royal Infirmary to see the nurses and do a round of bed cases. I also see what one might call "outpatients." The time taken varies, but is usually between 1 and 1½ hours.

No health examinations are done at this time; they are done by appointment as soon as possible after the arrival of each batch of nurses. These examinations are carried out in the nurses' home where their own teaching is done, and which, consequently, is fairly well equipped for the purpose.

From the Infirmary I go to the University buildings about two miles away, where I first of all see "outpatients," and then pay any necessary outdoor visits to students in their lodgings. I often return to their lodgings in the evenings to deal with the cases more thoroughly, and find that the necessary intimate relationship is better achieved at this than at any other time.

Routine health examinations of university students are also done by appointment. This is rather an important point. Each student is invited to make an appointment. This avoids interference with lectures and gives the student no excuse for not attending.

The health examination is fairly comprehensive, including a history of previous illness, family history, amount and kind of exercise, interests and hobbies, standard of lodgings as regards accommodation, food, suitability for work, price, &c.; a dark-room examination of ear, nose, mouth, throat, and fundus oculi; tests of visual acuity and colour-vision; clinical assessment of nutrition, posture, and development; hæmoglobin examination; radiography of chest, and examination of urine; and a general examination. An electrocardiograph will be utilised when a machine is available. Particular attention is paid to such things as dental caries, infected tonsils, chronic nasal catarrh and sinusitis, errors of

refraction and muscle balance, postural defects, skin eruptions, hæmorrhoids, varicose veins, defects of locomotion, and moderate degrees of anæmia, conditions which are apt to be neglected or to have their treatment postponed, but which if tackled early can prevent later trouble. Special care is directed to ingrowing toenails, flat-foot, hammer-toes, and other deformities, and to trophic conditions, chilblains, and erythrocyanosis. The nurse inquires particularly regarding menstrual disorders; and, by arrangement with the professor of gynæcology, all such cases are referred to his department for thorough investigation by a woman doctor.

All defects found which require further specialist examination and treatment are referred to the special departments of the Royal Infirmary. The honorary staff are extremely helpful, the specialists concerned affording students reasonable priority and sending useful reports on their cases. Radiography is done at the Royal Infirmary at certain fixed times daily.

Arrangements for dental treatment are not yet comprehensive. Particular cases, such as dental cysts and impacted teeth, are referred to the dental surgeon on the staff of the Royal Infirmary; for ordinary treatment they go to local dental practitioners. Psychological cases are referred to the mental-health department of the Royal Infirmary. Cases of underdevelopment and postural defects are referred to the director of physical training. All findings, together with specialists' reports, are recorded on a punch-system record-card and filed under appropriate headings for easy reference.

PHYSICAL EXERCISE

I have been astonished at the number of students who take no outdoor exercise at all. The percentage of those who do not take enough exercise is very high, about 80% of those examined, and of this group a considerable number appear to have no sort of hobby or interest outside their work as students. This is surely a serious matter. It is not the physician's concern to take part in producing athletic champions, but he should be concerned to see that those who are not able to secure a place in the first and second teams should be able to enjoy periodically a vigorous healthy game or other exercise.

It is generally agreed that young people in this age-group should have plenty of opportunity for letting off steam in exercise of one kind or another. Those who do not like games can seek other forms of recreation, but it should be in the open air. This applies particularly to students whose work is essentially indoors and sedentary, sitting in class-rooms, looking down microscopes, standing round a bed or in the operating-theatre. I feel that many of the student's troubles would disappear if his life were better balanced and he took more physical exercise. No university health service is complete which does not deal with this important aspect of student health. My own contact with the athletic union is not so close as it should be, but I hope to come to some arrangement whereby I can achieve a measure of "direction" towards the playing-fields or the open country for those students who at present lack the opportunity.

ORGANISATION

The University of Aberdeen has been generous about equipment, but the question of supply has been difficult and my rooms are not yet completely equipped. Accommodation and equipment should be adequate if the health service is to attain the high standard consistent with a university service; no physician can put out his best work if he is handicapped in this respect.

As regards the cost of treatment, a student admitted to the Royal Infirmary or attending a special department is dealt with in exactly the same way as other patients. The University has laid down that it "will only accept minor financial responsibility in connexion with the treatment of students." This leaves a good deal to the interpretation, and I have taken it that the University will cover the cost of what I use in the treatment room, but that the student must pay for any drugs and dressings he may require for use in his home or lodgings. There are several funds at the disposal of the University authorities designed to help necessitous students in sickness, but they can be called on only for serious cases and do not cover the sundry small sums required in the ordinary way. Such things as sulphonamides and most of the useful remedies and dressings can make quite a bite into a student's weekly pocket-money, but it is surprising how rarely it is necessary to prescribe drugs; and, as regards dressings, students who are coming to the University every day can easily call in at the treatment room, where the nurse will do their dressings for them. Under the Health Act all sickness costs will be met.

The staff at the University centre consists at present of myself and a nurse-secretary. If the work increases it may be necessary to have a nurse and a secretary. The flat at the Royal Infirmary is in charge of a permanent nursing sister, and the nurses are found and changed in the ordinary way by the Infirmary authorities.

To what extent can this staff and the arrangements which I have outlined meet the need for the yearly routine health examination of all students in the University, in addition to their care in sickness? In other words, are they sufficient for a comprehensive service? The problem is largely mathematical and depends to some extent on the number of students coming for examination.

It takes a minimum of 40 min. to examine a student properly. Allowing for the time necessary to visit the Infirmary in the morning, often again in the evening, and for occasional return visits to see members of the staff, &c., to deal with sick students and visit them in their lodgings, and for sundry distractions incidental to the service, I can examine, on an average, 6 cases a day, or about 30 a week.

There are three full terms of about 9 weeks ..	810
In the Christmas and Easter vacations it would be possible to examine a further 100 students resident locally	100
About 150 medical students come up for vacation terms in their last 2 years of study	150
	1060

This is probably the maximum of examinations which could be carried out by one whole-time physician, and to do this he would require an efficient nurse or an assistant capable of doing some accurate technical work such as examination of urine, Hb estimations, electrocardiography, &c., and a secretary. With any larger number than this there would be no alternative to increasing the staff. The numbers dealt with could, however, be more than doubled if two full-time physicians were employed, since there would not be the same distraction and break in the work. Examinations subsequent to the first do not occupy so much time, and half-hourly appointments could be made. Two physicians, with additional accommodation, could manage 2500 examinations yearly.

In Aberdeen University there are, in the present year, 1822 matriculated students; hence one physician could not carry out the work of a full medical service on the basis of a yearly examination of all students. Should examinations be limited to first-year and third-year students in all faculties, and fifth-year and final-year medical students, the number to be examined next year would be about 1050. I consider that one physician could do this and look after sick students also, but the numbers in the third and subsequent years are likely to increase after next year.

At present health examinations are compulsory only for medical students, who have to be examined three times during their course, and voluntary for all others.

The number of non-medical students likely to volunteer cannot yet be estimated, since in this broken year I have only been able to approach those in their first year; of these 28% requested examination and were examined. Taking 30% as a likely response for all non-medical students, the number of examinations, on a yearly basis, would be about 1050 on this year's figures, with, in addition, 75–100 nurses.

The examination of the nurses can be carried out more quickly than that of the students, because the examinations are done in the nurses' home, where they are paraded and prepared—i.e., they are brought in one after another in dressing-gowns. The sister tutors also are able to help considerably with measurements of height and weight, examination of urine, &c.

There is a striking difference between the university student and the student nurse. The nurse is more carefree and less worried. She is governed completely from the time she enters hospital, her day's work and her hours of recreation are planned, her quarters and meals provided, she wears a particular kind of clothing, and she subjugates herself entirely to hospital discipline. She has little privacy, even in illness; she reports sick through the matron, is conducted to the doctor by a sister, and full information of her condition goes back to matron and to her family. Her studies are carefully supervised. She receives a wage sufficient for her immediate needs. In fact, her behaviour generally is ordered and she has relatively little to worry about.

The university student is much more intense, more inclined to introspection and worry. His course of study is planned, but it is a much more exacting affair than the nurse's. He is very much more on his own (indeed I have found that the student can be a very lonely person) and has nothing provided in the way the nurse has. He receives no salary and is often hard put to it to make ends meet.

Because of the difference between these groups I am a little doubtful at the moment of the value of incorporating the care of student nurses in a university student-health service, but must reserve opinion pending further experience, or pending a change in the training of nurses.

COMMENTS

The preventive value of the service is beyond question. It is obviously of the first importance that students of all faculties should be able to continue their studies unbroken by sickness. It is also very important that, if sick, they should be made sufficiently well to sit examinations at the proper time. One fascinating element of the work lies in the frequent efforts to effect a cure against time. Life at a university ought to be, and I think usually is, for the student a happy and healthy time. On the other hand, the conditions which students make for themselves can be very depressing both mentally and physically. The fog-banks ahead in the form of examinations, the feeling that one is not keeping pace with the teaching, the abandonment of physical exercise to devote more time to work, the effort to put in more hours of reading continuing into the "wee sma' hours," the subsequent heaviness on waking and the scramble to get to the first lectures in time, the consequent irregularity of bowel movement, bad landladies, uncomfortable "digs," poor food, and often financial stringency, all these and other factors are common in a student's life and do not make for fitness.

Clear sound advice, especially insistence on the need for engaging in sport or taking exercise in some suitable form, and its value as a means of mental relaxation, on the value of the weekend and of the vacation, the correction of headaches and eye strain and of other small but important defects, the assurance that certain sexual disturbances are of small significance, and in many cases just letting the student unburden himself—all these can do a great deal to assist him to come fresh to his final examinations and fit to face whatever the world has in store for him thereafter.

My main criticism of the service is that it will be incomplete until health examination is made compulsory not only for medical students but also for students of all faculties. Though to many people the idea of compulsion is distasteful, I am strongly in favour of making a complete medical examination compulsory for all students. In this free country compulsion enters so largely into our lives that I cannot believe there would be any difficulty about it; nor is there any evidence that students themselves would resent it. So far as medical students are concerned, they all come along in a cheerful frame of mind, and I have not met one who showed resentment at having to be examined. The reason why more students do not present themselves voluntarily is that they "cannot be bothered"—the common evasion of these often casual young people.

Another reason which tends to make the service incomplete, and one which must affect the statistical analysis, is that in Aberdeen (and I suppose the same applies to most universities other than Oxford and Cambridge) many students live with their parents in the town and, when ill, consult their own family doctor. In fact the terms of employment of the physician are that he will attend "those students whose homes are not in Aberdeen" and are living in lodgings. Some students, however, who have family doctors in Aberdeen consult the University service for treatment. I take the opportunity of examining all who come, from whatever source, very thoroughly. Minor ailments are dealt with on the spot; with regard to anything more serious, I make a point of getting in touch with the practitioners concerned, some of whom ask me to deal with the case; others treat the student and keep me informed, but in a few cases I lose touch completely. As an example, a case of early pulmonary tuberculosis detected on routine examination was referred to his own doctor, who elected to deal with him, and I have not been able to get an accurate report on his progress. On the whole, however, the practitioners in Aberdeen are friendly and coöperative, and some of them who are consulted direct refer cases to me or tell me about them. The situation constitutes a potential source of leakage, and I see no way to overcome it other than by seeking to maintain friendly relations with all concerned. The University chaplain and the supervisor of women students sometimes hear of sick students when I do not, and are helpful in putting me in touch with cases.

Though a student-health service has been in operation in Aberdeen for some time, the present full-time service is in its infancy, and experience so far may not be a complete guide. The fact that the service has not been well known to students, difficulties in obtaining equipment, and other things have affected the work, and the experience of at least another full academic year will probably be required before one can speak in exact terms of what can be done.

CONCLUSIONS

The student-health service should, so far as possible, be complete.

The provision of medical care—i.e., involving the full doctor-patient relationship—affords the best means of getting complete and accurate records of the social and environmental background and of individual histories.

There should be a sanatorium or special accommodation in hospital for students, and it is desirable that the physician in charge of the service should have charge of this.

A full-time physician in charge of a full service can carry out 1000 examinations per year.

The examination should be compulsory for students of all faculties.

COMPULSORY PHYSICAL EDUCATION FOR UNIVERSITY STUDENTS

R. H. BOLTON
B.M. Oxfd
MEDICAL OFFICER TO THE UNIVERSITY OF BIRMINGHAM

If its more specified purposes are set aside, university education may be considered as the ordered pursuit of advanced knowledge and techniques, with a bias towards contemporary social purpose. The subject of this paper is simply the physical aspect of this pursuit so far as it affects the undergraduate.

It will help first to consider briefly the whole field of physical education and compare it with the parallel stages of an intellectual discipline. Thus, the primary stage may be said to correspond with the acquisition of the techniques of reading, writing, and arithmetic. The child learns elementary bodily coördination in an environment governed by simple natural laws. Running, jumping, throwing, and climbing are the primitive skills at this stage, but one may add catching, floating in water, or bouncing, to illustrate the gradually increasing perplexity of the natural forces involved.

The secondary stage, which follows the acquisition of "physical literacy," is the stage of "tools and conventions." Just as, intellectually, the child uses the tools of mathematics and language to broaden its skill and assimilate previous human experience in relation to present needs, so physically he starts to use the tools which relate him to more complex natural forces, and to learn the conventions of contemporary games. For instance, he may use a bat, a swing, skates, skis, a springboard, or a sail to play off one physical force against another to serve his purpose, much as the budding craftsman learns how the momentum of a mallet and the cutting end of a chisel combine to produce the configuration of wood which he requires. And he must also learn the rules of games whereby he relates his skill to that of others, coöperating with or outwitting his fellows in turn.

By the time the university stage is reached, the student should have acquired both elementary skill and experience. The next stage is to be regarded as one of differentiation rather than growth. The student should know his or her capabilities and be able to specialise to some extent in those pursuits to which he or she is temperamentally or physically best suited. But at the same time a new characteristic tends to emerge—that of social maturity. Thus, while skill may be specialised, character is broadened. Instead of playing football when football is laid on for him, he plays, if he is keen, as a member of a club, and the running and fortunes of the club become partly his concern. The physical skill is thus related to social function. Courts must be booked, expeditions organised, the hard work of maintaining equipment and taking turns in the use of it bring valuable qualities to the fore in addition to the much vaunted team spirit. Moreover, purely social contacts mature from these associations and are complementary to those fostered simultaneously by kindred intellectual pursuits or communal living conditions. In the desire to arouse the interest of others and encourage their skill is discovered the germ of the teaching attitude.

This brief analysis, the divisions within which are very arbitrary, shows the lines on which an ideal university physical-education department might work. It should provide for the integration of physical activity with personality and society on as broad a basis as possible, without detriment to an ordered freedom consonant with the university attitude. It makes three basic demands: freshmen with elementary skill and secondary experience; ample and varied equipment; and "academic" standards of teaching and opportunity.

DEFECTS OF VOLUNTARY SYSTEM

At this point we come to the three major difficulties inherent in this utopian project, for in practice we find many freshmen with no experience and some even with no elementary skill. We find also equipment that is ample in only a few narrow fields and entirely lacking in others; while the teaching, where there is any, can seldom by any stretch of the imagination be considered as of academic standard.

These three difficulties relate ultimately to one another; the poor quality of teaching with few facilities in the schools allows the physical illiterates to reach the university, which in turn has no standards of its own. That this vicious circle is overlooked must be attributed in large measure to the voluntary system which fosters the emergence of the ready-skilled few and stifles the moderate potential of the many.

This voluntary system is voluntary only in name, for the student is—at least in some older universities—virtually compelled to contribute a considerable subscription to the sports funds, which are all spent on the pursuits of rowing, cricket, and football. If by inclination or time-table these are not feasible in his case, he is destined to fend for himself in the open market of an overcrowded and ill-provided town. Let us accept that this is a bad old tradition. But the tradition of the younger universities is no better, for here the idea seems to have been that anything the student did, or did not do, out of academic hours was no concern of the university. These various traditions at present combine in depriving something approaching 90% of all university students of adequate physical opportunity.

WIDER CHOICE WITH COMPULSION

If we are to overcome inertia in this matter and catch up with the times, a complete change of attitude will be necessary. Education for the body as well as the mind must become a concern of the universities, and my own view, supported by experience, favours the introduction of compulsory physical activities for all first-year students. I have changed my mind in this matter in the last two years, and I hope to persuade those who disagree to change theirs, for I have seen what has already been accomplished by this means by my colleague A. D. Munrow, director of physical education at Birmingham University, to whom I owe many of the views here advocated. It is his experience that the compulsion falls far more heavily on the university authorities than on the student. He has, for instance, had to be provided with increased facilities, a threefold increase in his original staff, and adequate time from the curriculum hours for physical activity. He is, I need hardly say, possessed of considerable vision and powers of inspiration, and has collected first-rate assistants, but he found that the old system gave him no opportunity to realise his ideas. The choice provided is large and the system is popular; it interferes in no way with the usual games and sports run by student organisations whose regular players can contract out of the compulsory periods if they wish.

The alternatives include camping, rock-climbing, folk-dancing, and gymnastics; and, during the past hard winter, skis were obtained from Government surplus stores, and cross-country expeditions were organised. The social value of physical education, thus broadly conceived, is one of its major assets.

The native resentment to compulsion is, after all, something of a bogy. We compel students to attend their courses, once chosen; and we often compel residence in halls or colleges, and conformity with a host of regulations for the sake of equable community living. Why should we not also compel a health-promoting régime for the same reason? If compulsion is so bad for the body, is it not worse for the mind?

Compulsory physical education is not likely to be adopted immediately by all universities; it is in an experimental stage and merely represents one view of future developments. For one thing, there is at present no adequate staff available of the required quality. Physical education has suffered badly from dogmatism; rigid systems have been built up on unproved hypotheses, and often applied in unsuitable conditions. Much of my time is given to contradicting the false theory that permeates the textbooks. The products of physical-training colleges are too often narrow-minded; and though some of these colleges have doubtless done valuable pioneering work, they seem to cling to systems of drill and gymnastics, founded on mythical principles, with unswerving tenacity. We need a much more liberal and scientific attitude in this matter.

It is to be hoped that other British universities will accept physical education as a subject worthy of a place beside purely intellectual subjects in a general degree course, and thereby encourage some of those gifted young men and women who combine physical and intellectual skill to take up a career that provides a field for both. For, surely, physical education is both a means and an end in itself, like any other branch of education; its merits, alike for the individual and society, must equally be taken for granted and not tied to any particular physiological hypothesis. The objective of both bodily and mental training is the better education of the "whole man." Of two equally erudite professors, the one who plays squash or can dance a foursome reel is the better product.

Let us therefore see that our universities set about providing for a much wider range of physical skills: not only field and court games but all-the-year-round swimming and diving; dance, both traditional and contemporary; not only athletics and gymnastics but also skating, ski-ing, gliding, and sailing; not only S.T.C. camps but expeditions for adventure, mountaineering, and canoeing. These are all worth-while activities whose virtues are not in question among those who pursue them or those who have given time and thought to their encouragement. Can we doctors honestly say that we know any better?

HEALTH EXAMINATIONS OF STUDENTS

PILOT SURVEY IN OXFORD

R. W. PARNELL
B.M. Oxfd, M.R.C.P.
PHYSICIAN IN CHARGE OF STUDENT-HEALTH SERVICE, INSTITUTE OF SOCIAL MEDICINE, OXFORD

THE purpose of this communication is to relate experience of a pilot survey of student health carried out during the first two terms in 1947 at Oxford, and to examine in the light of this experience what degree of success student-health examinations may expect, and what the limitations of this method are in practice.

The scheme which operates at Magdalen and Somerville is designed to provide health examinations and a health advisory service for the undergraduates of these colleges and to carry out a long-term study of their health. The physician in charge does not undertake treatment, except in so far as explanation and reassurance may be necessary. The specialist services at Oxford have been of great help from the beginning. Good ancillary services are available at most universities, but it should be emphasised that for each student in need of treatment in term time at least an equal number have minor anxieties or need advice on general lines. There are consequently many opportunities of usefulness to be found by a medical adviser who is independent in the student's mind of parental, tutorial, or disciplinary relationship and can be consulted at any time without additional cost.

During Hilary and Trinity terms this year 155 students were examined on a voluntary basis, 77 from Magdalen and 78 from Somerville. This represents 60% of first-year men and 66% of first-year women to whom the invitation to join was sent. Rather more were seen in Hilary than Trinity term, when pleasanter outside diversions abound, and the response among first-year students was rather higher than among those in their second year.

The ideal time for the first approach appears to be just before arrival in the first year, before the students are bombarded with political and other circulars. Though this early approach was made impossible by starting in January, the response may be regarded as encouraging; unfortunately it is insufficient to yield a representative survey of the two colleges, and it is doubtful whether this is possible on a voluntary basis.

Experience elsewhere has led to the recommendation of compulsory medical examination. Medical examination should not constitute an extra condition of entry to university life; nor should it ever appear to influence a student's progress at the university adversely. On the contrary, it offers benefits, such as the early recognition of serious and remediable illness and the correction of minor defects which can interfere with work and enjoyment. A fair number of undergraduates have volunteered the view that health examination should be compulsory, and if the opposition to this is greater in senior than in junior common-rooms it is believed to arise in part from a fear of making neurotic students. Experience in the fighting services does not confirm this conjecture, and the work of the M.O. in support of morale is well recognised. It is no part of the design of the scheme to pander to moral weakness, or to recommend as a rule deep delving of a psycho-analytical type, except in the rare instances in which such specialist help may prove necessary. Far more often opportunity is found to relieve anxiety at an early stage.

Another fear is that further filching of the personal liberties of the individual may be attempted, an ugly enough symptom which is thought to be extending today. Health examination at the university is surely no more of an infringement of this liberty than are the recognised services of the school doctor, of whose work it is a logical extension, and it is even less of an infringement than in the case of the medical services of the fighting forces, where medical examination at entry may prove a dispiriting bar to opportunity.

Further, in the student-health scheme no outside loyalty need exist which might influence the relationship between student and doctor. When fully established in university life it seems more probable that the doctor may find that he has to resist pressure by college or university administration to open the medical back-door in the case of students failing to profit or for other reasons undesirable.

The great advantages of compulsion are (1) the assurance that so far as possible all handicaps are discovered and dealt with; and (2) the information which becomes available concerning the health and sickness experience of students would be representative. For study purposes and for the planning of health apparatus in general a fair sample then replaces one in which other non-random methods of selection have occurred.

FINDINGS OF PILOT SURVEY

For those still in doubt of the need for student-health supervision, perhaps the findings in this pilot survey at Oxford may provide convincing evidence. They record many minor and remediable disabilities and not a few serious illnesses among 155 students, in spite of the belief that as a group they should represent one of the healthiest sections of the community. Altogether of 155 students, 23 (15%) were deemed to need treatment before the end of term; in another 61 (39%) it could be postponed till the vacation.

Among the more important abnormalities discovered by the survey of 155 students were:

(1) One case of open pulmonary tuberculosis, and another with pleural effusion and tuberculous foci. Notification of the first led to discovery of a younger brother with active infection. From a public-health point of view isolation of infective cases is clearly desirable, and yet at present a medical officer of health may have knowledge of such cases in a university population but lack the liberty to inform college authorities.

(2) Systolic murmur because of which activities had been limited ten years previously. Reassurance led to full restoration.

(3) Attacks of abdominal pain requiring investigation. Follow-up examination of amœbic dysentery and sprue.

(4) Iron-deficiency anæmia (two cases, Hb 55%, Hb 76%).

(5) Polyarthritis secondary to nasal polypi and sinus infection. Osteochondritis of lumbar spine with symptoms. Internal derangement of the knee. Recurrent dislocation of the shoulder.

(6) Transient inferior rectus palsy, with diplopia.

(7) Twenty cases of minor anxiety open to relief by explanation and reassurance.

The accompanying table of classified findings indicates which abnormalities are most common. Dental care on the whole was good, but the number of students recognised to be in need of dental treatment might well have been higher had probe and minor examinations been carried out by a dental surgeon. About three-quarters of those with errors of refraction had already been diagnosed, but annual re-examination may bring to light some progress in these defects. A family history of migraine, asthma, or eczema was present in 28%.

AIMS OF STUDENT-HEALTH EXAMINATION

Apart from assessments which lead to the removal of physical handicaps, the aims of the health examination must be concerned in some degree with the assessment of personality and those social conditions which control a student's life. If suitable records are devised, especially if certain evidence relating to background and upbringing is included, it will become possible in time to determine the influence of factors such as social origin, family history, previous illness and constitutional tendency, "only childism" (more than 1 in 5 of recent entries at Oxford have been only children), economic status, type of schooling, nature of lodging, opportunity for physical exercise and hours spent in daily travel, and to plot the bearing of such factors on health and successful use of university opportunity. Such records should also provide evidence from which advice on community problems of diet, lodgings, work, and recreation may be given, and furnish indications about the most profitable aspects of physical or mental hygiene to treat in lectures. There is, however, one important aspect in the making of such records which should not be neglected. It is desirable to shape, with the assistance of the statistician and expert records officer, a form which might become general in all universities, providing certain basic information of a factual kind in a manner readily susceptible of analysis. The use of such a card in no way precludes ad-hoc investigations of local choice. It would allow of valuable comparisons between universities and furnish material for the establishment of useful standards.

CLASSIFIED FINDINGS IN 155 STUDENTS

Condition	No. of male students	No. of female students	Total
Eye:			
Myopia	27	24	51 (*33*%)

LIMITATIONS OF THE METHOD OF ROUTINE HEALTH EXAMINATION

Time is the most important factor. One hour was devoted to the interview and examination, including hæmoglobin estimation; of this it is as well to keep 10 minutes at the end for discussion of the findings and those important last-minute questions which a patient asks when his confidence is fully established. Chest radiograms are taken for convenience on a separate occasion. If taken beforehand and reported as normal they serve as a useful method of opening the interview. A maximum of 20 patients a week can be seen as a regular procedure, and the number of 1-hour examinations in a year is limited to a maximum of 450 where there are three 8-week terms. This means that if 1 hour were to be devoted to each annual re-examination, and the average stay at the university is 3 years, the annual entry which could be handled by one physician would be about 150. Where university terms are longer than 8 weeks, up to 250 might be a reasonable annual quota.

Now, if it is desired that the doctor supervise more than this number, a point will be reached at which this type of health examination, which is more suitable for research purposes, should go by the board and be replaced by another less time-consuming. One suggestion is that the more important headings could be extracted and embodied in a shortened form suitable for a half-hour interview. It is reasonable to suggest that most of the more important abnormalities would have been detected at a half-hour interview, provided that concentration was kept on their discovery. A number of headings such as addresses, schools, and experience in the Forces may be completed by a secretary-receptionist. Much time is saved if the student is provided with headings of previous history to complete at leisure beforehand, and this too often serves to crystallise in his mind some problem on which he wants advice.

What criticism may be offered of this briefer type of interview? It would hurry the proceedings and make the discovery of an abnormality prejudice the time-table. Thus it would not permit to the same degree the patient, accurate, and complete recording of data without which analysis and correlation would be valueless, though there should be no difficulty in recording such essential measurements as height and weight. With regard to the number of patients who could be seen, it certainly would not double this, though it would allow some increase. Despite these criticisms, if the half-hour consultation leads to the removal of the defects which can be remedied it will have served its main purpose.

If it is impossible to devote half an hour to each student, it might be better to limit the health service to routine chest radiography and facilities for consultation for those who complain or have some special problem they wish to discuss.

An alternative method for dealing with large numbers might be the setting up of a university medical board with an ophthalmologist and aural and dental surgeons in attendance. This immediately raises problems of expense, accommodation, and administration, together with the risk of some loss in the personal relationship between physician and student. Medical work in these circumstances for a long period is also apt to lose its hold over the doctor's interest.

As a last note, it should be emphasised that the life blood of routine health examination, especially when practised as a whole-time job, *flows only so long as the* channels of interest in the individual are open; should these be choked by an undue burden of routine, the value of health examinations must quickly decline. Where, on the other hand, time is available for interest to develop in the individual student, it grows greatly and the work as a whole seems more than worth while.

My thanks are due to Sir Henry Tizard, late president of Magdalen College, and to Dr. Janet Vaughan, principal of Somerville College, who helped to make this pilot survey possible. I am particularly grateful to Prof. J. A. Ryle for the benefit of his direction and criticism.

FAMILIAL IDIOPATHIC METHÆMOGLOBINÆMIA

FIVE CASES IN ONE FAMILY

QUENTIN H. GIBSON
M.D., Ph.D. Belf.
LECTURER IN PHYSIOLOGY

DOUGLAS C. HARRISON
D.Sc. Lond., Ph.D. Camb.
PROFESSOR OF BIO-CHEMISTRY

QUEEN'S UNIVERSITY, BELFAST

VERY few instances of idiopathic methæmoglobinæmia occurring as a familial disease have so far been reported. Deeny et al. (1943) described the condition in two brothers and found that the disease could be successfully treated with large doses of ascorbic acid, as had been found independently by Lian et al. (1939). Barcroft et al. (1945) made a detailed study of Deeny's cases during treatment and reviewed the literature of the disease up to 1940. Since then there have been reports of isolated cases treated successfully with ascorbic acid (King et al. 1944) and with methylene-blue and ascorbic acid (Sievers and Ryon 1945).

The cases reported here come from a family of nine brothers and sisters, five of whom are affected, a number larger than has been definitely authenticated in any family previously described. The effects of treatment are recorded, together with the results of biochemical investigations which throw light on the underlying metabolic abnormality responsible for the condition. The observations on this family may also provide material for genetic studies.

The family is set out in fig. 1. No. 6 came under observation first when he attended the outpatient department of a general hospital for a minor injury. He was referred to us because of his cyanosis, and we found that his blood contained a considerable amount of methæmoglobin. He was treated with ascorbic acid 300 mg. daily. The changes in his blood-methæmoglobin level during treatment are shown in fig. 2. He did not appear to be greatly concerned about his unusual colour and did not continue treatment. When we saw him four years later he had relapsed completely, having taken no ascorbic acid for at least eight months. We could not secure any satisfactory family history from him and at the time regarded him as an isolated case.

In 1946 his identical twin brother, no. 7, attended hospital for an injury to his hand and was similarly referred to us because of his cyanosis. We found methæmoglobin in his blood, and he told us that several other members of his family were abnormal in colour. They were so little concerned about their appearance that we could not persuade them to come to hospital for investigation and treatment.

We were anxious, in view of the rarity of the disease, to obtain all the information we could about the whole family. We therefore decided to visit them. They lived on a small farm in a remote and mountainous part of Ireland; and, since it is necessary in measuring methæmoglobin to carry out the determinations as soon as possible after taking the blood samples, we set out in a car fitted up as a mobile laboratory. The equipment included a Spekker photo-electric absorptiometer and a Beck-Hartridge reversion spectroscope, both modified to work from the car accumulator. The family were most coöperative, and we obtained blood samples from all the living members of the family except one whom we could not reach.

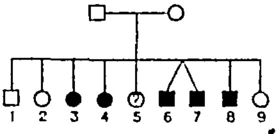

Fig. 1 — Familial idiopathic methæmoglobinæmia: affected males shown by black squares; affected females by black circles; nos. of members of the family correspond to those in the table.

ANALYSIS OF BLOOD PIGMENTS

Venous samples were taken from the arm and put into tubes containing potassium and ammonium oxalate mixture. They were kept ice-cold until analysed for methæmoglobin about two hours later. The blood samples were examined in the reversion spectroscope. Those from the cyanosed members of the family all showed an absorption band in the red, the mid-point of the band being at 633–634 mμ indicating the presence of methæmoglobin. The band was clearly visible in a dilution of 1 in 40 when viewed in a thickness of 2 cm.

Methæmoglobin was determined photo-electrically by a method based on that of Evelyn and Malloy (1938), which depends on the increase in transmission of red light when methæmoglobin is removed by addition of cyanide. Blood 0·6 ml. is added to 16 ml. of distilled water; and, after it has stood for 10 min., 8 ml. of $M/10$ phosphate buffer (pH 6·9) is added. It is preferable to centrifuge the mixture strongly for 20 min. at this stage. We have found it a great advantage, when measuring small amounts of methæmoglobin, to use a differential method of reading in the absorptiometer. The solution is put into two similar 1-cm. glass cells, which are read one against the other. The cyanide is then added to one and the reading repeated. From the change in absorption, the methæmoglobin is found from a calibration curve prepared in the same way from blood containing various known amounts of methæmoglobin.

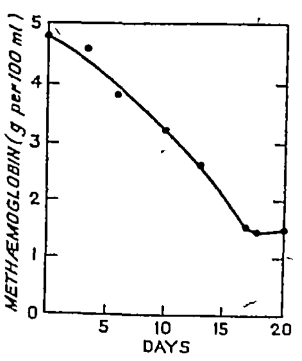

Fig. 2 — Changes in blood-methæmoglobin level in no. 6 during treatment with ascorbic acid 300 mg. a day.

Total blood pigments were determined by the alkaline-hæmatin method using the artificial standard of Gibson and Harrison (1945).

The accompanying table shows the blood-methæmoglobin levels of all members of the family except no. 1, who was away from home but was stated independently by three members of his family to be normal and never before the end of term; in another 61 (39%) it could be postponed till the vacation.

Among the more important abnormalities discovered by the survey of 155 students were:

(1) One case of open pulmonary tuberculosis, and another with pleural effusion and tuberculous foci. Notification of the first led to discovery of a younger brother with active infection. From a public-health point of view isolation of infective cases is clearly desirable, and yet at present a medical officer of health may have knowledge of such cases in a university population but lack the liberty to inform college authorities.

(2) Systolic murmur because of which activities had been limited ten years previously. Reassurance led to full restoration.

(3) Attacks of abdominal pain requiring investigation. Follow-up examination of amœbic dysentery and sprue.

(4) Iron-deficiency anæmia (two cases, Hb 55%, Hb 76%).

(5) Polyarthritis secondary to nasal polypi and sinus infection. Osteochondritis of lumbar spine with symptoms. Internal derangement of the knee. Recurrent dislocation of the shoulder.

(6) Transient inferior rectus palsy, with diplopia.

(7) Twenty cases of minor anxiety open to relief by explanation and reassurance.

The accompanying table of classified findings indicates which abnormalities are most common. Dental care on the whole was good, but the number of students recognised to be in need of dental treatment might well have been higher had probe and minor examinations been carried out by a dental surgeon. About three-quarters of those with errors of refraction had already been diagnosed, but annual re-examination may bring to light some progress in these defects. A family history of migraine, asthma, or eczema was present in 28%.

AIMS OF STUDENT-HEALTH EXAMINATION

Apart from assessments which lead to the removal of physical handicaps, the aims of the health examination must be concerned in some degree with the assessment of personality and those social conditions which control a student's life. If suitable records are devised, especially if certain evidence relating to background and upbringing is included, it will become possible in time to determine the influence of factors such as social origin, family history, previous illness and constitutional tendency, "only childism" (more than 1 in 5 of recent entries at Oxford have been only children), economic status, type of schooling, nature of lodging, opportunity for physical exercise and hours spent in daily travel, and to plot the bearing of such factors on health and successful use of university opportunity. Such records should also provide evidence from which advice on community problems of diet, lodgings, work, and recreation may be given, and furnish indications about the most profitable aspects of physical or mental hygiene to treat in lectures. There is, however, one important aspect in the making of such records which should not be neglected. It is desirable to shape, with the assistance of the statistician and expert records officer, a form which might become general in all universities, providing certain basic information of a factual kind in a manner readily susceptible of analysis. The use of such a card in no way precludes ad-hoc investigations of local choice. It would allow of valuable comparisons between universities and furnish material for the establishment of useful standards.

LIMITATIONS OF THE METHOD OF ROUTINE HEALTH EXAMINATION

Time is the most important factor. One hour was devoted to the interview and examination, including hæmoglobin estimation; of this it is as well to keep 10 minutes at the end for discussion of the findings and those important last-minute questions which a patient asks when his confidence is fully established. Chest radiograms are taken for convenience on a separate occasion. If taken beforehand and reported as normal they serve as a useful method of opening the interview. A maximum of 20 patients a week can be seen as a regular procedure, and the number of 1-hour examinations in a year is limited to a maximum of 450 where there are three 8-week terms. This means that if 1 hour were to be devoted to each annual re-examination, and the average stay at the university is 3 years, the annual entry which could be handled by one physician would be about 150. Where university terms are longer than 8 weeks, up to 250 might be a reasonable annual quota.

Now, if it is desired that the doctor supervise more than this number, a point will be reached at which this type of health examination, which is more suitable for research purposes, should go by the board and be replaced by another less time-consuming. One suggestion is that the more important headings could be extracted and embodied in a shortened form suitable for a half-hour interview. It is reasonable to suggest that most of the more important abnormalities would have been detected at a half-hour interview, provided that concentration was kept on their discovery. A number of headings such as addresses, schools, and experience in the Forces may be completed by a secretary-receptionist. Much time is saved if the student is provided with headings of previous history to complete at leisure beforehand, and this too often serves to crystallise in his mind some problem on which he wants advice.

What criticism may be offered of this briefer type of interview? It would hurry the proceedings and make the discovery of an abnormality prejudice the time-table. Thus it would not permit to the same degree the patient, accurate, and complete recording of data without which analysis and correlation would be valueless, though there should be no difficulty in recording such essential measurements as height and weight. With regard to the number of patients who could be seen, it certainly would not double this, though it would allow some of methæmoglobin in the blood. There would then be two kinds of corpuscles in the circulation, one containing normal (ferrous) hæmoglobin molecules, and one containing 100% methæmoglobin (ferric). In these circumstances there would be no opportunity for the two types of pigment to interact, and the oxygen-dissociation curve would be expected to be normal in position. In fact, however, as shown in fig. 3, the curve is shifted away from normal to the left. This hypothesis of the production of two types of corpuscle is thus evidently wrong. It seems much more likely that in idiopathic methæmoglobinæmia the abnormal pigment is distributed evenly throughout the red cells of the body rather than segregated in individual cells. According to the theory of Darling and Roughton (1942), there will then be an exchange of electrons between ferrous and ferric atoms, leading to pigment molecules each containing both ferrous and ferric atoms. Such molecules, they believe, have a stronger affinity for oxygen than has ordinary ferrous hæmoglobin. The shift in the curve in our experiments would thus be explained.

We believe that the abnormal amount of methæmoglobin is not due to any bone-marrow defect but to a disturbance in the equilibrium hæmoglobin⇄methæmoglobin (including any intermediate compounds) which in normal blood is very far to the left. Work shortly to be published (Gibson) has led to the conclusion that the reduction of methæmoglobin in normal persons depends on the triose phosphoric and lactic enzymes of the erythrocytes. These enzymes function with cozymase and coenzyme factor I in bringing about methæmoglobin reduction. Examination of the erythrocytes taken from cases of idiopathic methæmoglobinæmia has shown that they are deficient in coenzyme factor I. The accumulation of large amounts of methæmoglobin in the blood is thought to be due to the inability of the enzyme systems to reduce it to hæmoglobin. As it is probable (Peters and Van Slyke 1931) that methæmoglobin is constantly being formed in the blood of normal persons, we may suppose that the equilibrium level of methæmoglobin will depend on the efficiency of the enzymes which remove it. When these enzyme systems are deficient, large amounts of methæmoglobin will be present in the blood.

The rapid removal of methæmoglobin from the blood after the administration of methylene-blue is probably due to the catalytic action of the dye, which causes methæmoglobin to be reduced by enzymes which are otherwise unable to bring about this reaction (Gibson unpublished). The action of ascorbic acid in altering the blood-methæmoglobin level seems to be due to a direct reaction between methæmoglobin and ascorbic acid (Gibson 1943). The reaction is comparatively slow. Even with the greatest concentration of ascorbic acid which it is possible to attain in the blood, the displacement of the equilibrium methæmoglobin ⇄ hæmoglobin in favour of hæmoglobin is not sufficiently great to lead to the complete disappearance of methæmoglobin from the blood. It has been found in practice that these cases of methæmoglobinæmia when treated with ascorbic acid tend to settle down at a level of about 1 g. of methæmoglobin per 100 ml. As indicated by the work of Sievers and Ryon (1945), this equilibrium value of blood methæmoglobin is similarly approached from the other side with ascorbic acid treatment after methylene-blue has been given.

As regards the treatment to be recommended, it has been shown by several workers (see Barcroft et al. 1945, King et al. 1944, Sievers and Ryon 1945) that the blood methæmoglobin of these patients can be kept at this low level with daily doses of ascorbic acid of about 0·3–0·4 g., and that under these conditions hardly any cyanosis can be detected. On the other hand, the action of a single dose of methylene-blue, even when taken by mouth, is much more rapid and complete, as shown in the table, but its action is only transitory. It seems preferable to recommend continuous treatment with ascorbic acid, a natural food constituent, rather than with methylene-blue, which might possibly have an unsuspected toxic action after prolonged dosage. We feel, however, that it may be desirable to supplement the action of ascorbic acid with an occasional dose of 0·3 g. of methylene-blue by mouth, particularly if, as the result of temporary failure to keep up the intake of ascorbic acid, the cyanosis shows signs of returning.

SUMMARY

Five cases of familial idiopathic methæmoglobinæmia in one family of nine brothers and sisters are described.

Treatment with methylene-blue and ascorbic acid by mouth was successful.

The oxygen-dissociation curve of blood from one of these patients showed a shift to the left.

The ætiology of the disease and the significance of the findings are discussed.

We wish to thank Dr. P. J. Courtney, whose coöperation did much to make the investigation possible, and Dr. S. I. Turkington, who generously placed the facilities of his ward at our disposal.

RH FACTOR AND HÆMOLYTIC DISEASE OF THE NEWBORN IN JERUSALEM JEWS

J. GUREVITCH
M.D. Brno

A. BRZEZINSKI
M.D. Paris

Z. POLISHUK
M.D. Naples

From the Rothschild Hadassah University Hospital, Jerusalem

EVER since the discovery of the rôle played by the Rh factor in the pathogenesis of erythroblastosis fœtalis (Levine and Katzin 1940) it has been apparent that a correlation exists between the frequency of hæmolytic disease of the newborn and the distribution of the Rh antigen in the population. The incidence of Rh-negative persons is about 15% in the white races as compared with 0·6–4·5% in the coloured races (table I). There seems to be little doubt that in races with a small ratio of Rh-negative persons, such as Indians (Ranganathan et al. 1946) and Chinese (Levine and Wong 1943), erythroblastosis fœtalis is rare or altogether absent.

Little has been published on the incidence of the Rh factor in Jews, though Lubinski et al. (1945) found 8·57% of Rh-negative persons in Jewish women in Canada. In a previous study Gurevitch (1945) reported an incidence of 15% Rh-negative in a group of 400 blood examinations in Jewish persons in Palestine. It must be emphasised that his material was carefully selected, comprising cases of hæmolytic disease of the newborn and related conditions from the whole of Palestine. In fact, out of this limited material, 15 cases of Rh incompatibility, with anti-Rh antibodies in 8 of them, were found.

The fact that erythroblastosis fœtalis is rare among Palestinian Jews led us to expect a low incidence of Rh-negative persons among them. The fact that the to have been blue. His present employer confirmed that he is free from any signs of cyanosis.

The mother had died some years previously, aged 48, but was stated never to have been cyanosed. We also visited her brother, who showed no cyanosis. One of her daughters stated that her mother had been very fat and had died of a "liver complaint," having been jaundiced for seven months before her death; there was no evidence to suggest that her blood had ever contained any abnormal amount of methæmoglobin.

The father's blood was also perfectly normal, as was that of three of his children, the finding of 0·1 g. of methæmoglobin per 100 ml. in the blood of no. 9 being within normal limits (Gibson and Harrison 1945).

The remaining five brothers and sisters all showed methæmoglobin in their blood in abnormal amounts in accord with their abnormal appearance. None of them seemed to suffer any appreciable physical disability from the presence of the abnormal pigment, but they all said they "felt better" as a result of treatment.

As regards age of onset of the cyanosis, no satisfactory history was obtained from any of the people affected, who seemed very uncertain about how long they had been blue. The general consensus of opinion suggested that the cyanosis had first appeared in adolescence. None of them is married. It was stated that no other relations of the family had ever shown any cyanosis.

The father said that both his own and his wife's family had lived in the village for generations, and that he was related to his wife—"fourth cousins or something of the sort."

FINDINGS IN FAMILY AFFECTED BY IDIOPATHIC METHÆMOGLOBINÆMIA

No.	Age (years)	Colour of skin	Initial met-Hb (g./100 ml.)	Total pigments (g./100 ml.)	Met-Hb as % of total pigments	Met-Hb after treatment (g./100 ml.)
Father	67	Normal	0·0	14·6	0	..
1	32	"	..	..	..	..
2	31	"	0·0	15·6	0	..
3	28	Lavender	3·1	15·3	20	0·1
4	27	Grey-blue	1·9	15·9	12	0·3
5*	..	..	..	..	..	..
6	22	Slaty-blue	4·8	18·7	26	1·3
7	22	"	5·1	18·8	27	0·5
8	21	Grey-blue	1·9	17·4	11	0·1
9	18	Normal	0·1	12·7	1	..

* Died of pertussis at 7 months.

This evidence, together with such other information as is available in the literature (see Barcroft et al. 1945), makes it very probable that this form of methæmoglobinæmia is inherited as a recessive character. The proportion of sibs affected in the present family is much higher than would be predicted on average for a recessive factor, but wide departures from the theoretical proportion would be expected in individual families.

TREATMENT

No. 6 received ascorbic acid only, 300 mg. a day by mouth, with the result shown in fig. 2. No. 7 received ascorbic acid 1 g. daily for two days followed by intravenous methylene-blue 75 mg. This was followed by rapid improvement, a blood sample taken 1½ hours later showing only 0·5 g. of methæmoglobin per 100 ml. Nos. 3, 4, and 8 received ascorbic acid 1 g. and methylene-blue 300 mg. by mouth in capsules. (The samples for the final blood analysis of nos. 3, 4, and 8 given in the table were taken 24 hours after the administration of the methylene-blue.) The ascorbic-acid intake was maintained at 1 g. a day for four days, and then reduced to 300 mg. a day. Methylene-blue by mouth appeared to be as effective as giving the dye by injection, and cleared the blood of methæmoglobin within a few hours. The rapid change to normal of the skin colour was very striking.

SHIFT IN OXYGEN-DISSOCIATION CURVE

Hitzenberger (1932) found that in familial idiopathic methæmoglobinæmia the oxygen-dissociation curve of the blood was shifted to the left—i.e., the blood gave up oxygen less readily than is normal at a given oxygen pressure. Darling and Roughton (1942) have shown that this shift occurs in hæmoglobin solutions containing methæmoglobin produced artificially both in vivo and in vitro. (We are grateful to Prof. H. Barcroft for calling our attention to these papers.) Darling and Roughton interpret the shift as being due to the presence, in a hæmoglobin-methæmoglobin mixture, of molecules containing both ferrous and ferric atoms in various atomic proportions.

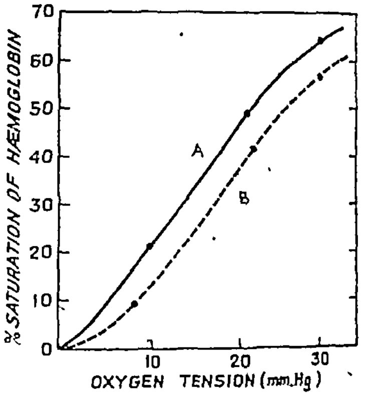

Fig. 3—Oxygen-dissociation curve of blood of no 7: A, with blood containing 4·2 g. of methæmoglobin per 100 ml.; B, with blood after removal of methæmoglobin by methylene-blue.

We determined the oxygen-dissociation curve in the blood of no. 7 by equilibrating the blood at 37°C with suitable mixtures of oxygen and nitrogen containing carbon dioxide at a pressure of 40 mm. Hg. Samples of the blood and of the gas mixtures were then withdrawn and analysed respectively in the Van Slyke-Neill apparatus and Haldane apparatus.

The shift in the dissociation curve was demonstrated in two ways:

(1) The dissociation curve of no. 7 was determined on the blood in the presence and absence of methæmoglobin. For this purpose a large sample of his blood was defibrinated by stirring with glass-wool and divided into two portions.

The methæmoglobin was removed from one portion by incubating at 37°C for an hour in the presence of 0·01 *M* glucose and 0·00005 *M* methylene-blue. (Control experiments showed that methylene-blue does not influence the dissociation curve of normal blood.) The same volume of glucose was added to the other portion but no methylene-blue.

The dissociation curves of both portions were then determined, with the results shown in fig. 3: the removal of the methæmoglobin produced a shift to the right in the position of the curve.

(2) The dissociation curve of the blood from no. 7 was compared directly with the oxygen-dissociation curve of a sample of normal blood. The results confirmed those obtained by removing methæmoglobin with methylene-blue, the curve for blood containing methæmoglobin being shifted to the left as compared with that of normal blood.

The shift in the dissociation curve and its change in shape from the S-shape characteristic of normal blood towards a hyperbolic form is of importance, since it would tend to make oxygen less readily available to the tissues. Thus, as Darling and Roughton (1942) point out, the substitution of the normal pigment by methæmoglobin would be expected to produce more severe effects than would a simple loss of the same amount of hæmoglobin.

DISCUSSION

The shift in the dissociation curve has a possible bearing on the interpretation of the mode of production of the abnormal pigments. One mechanism which might be postulated is that there is a defect in the bone-marrow leading to a production, by a part of it, of corpuscles containing only methæmoglobin, and that the proportion of abnormal bone-marrow determines the amount

MEMBRANOUS NATURE OF INTERSTITIAL CONNECTIVE TISSUE

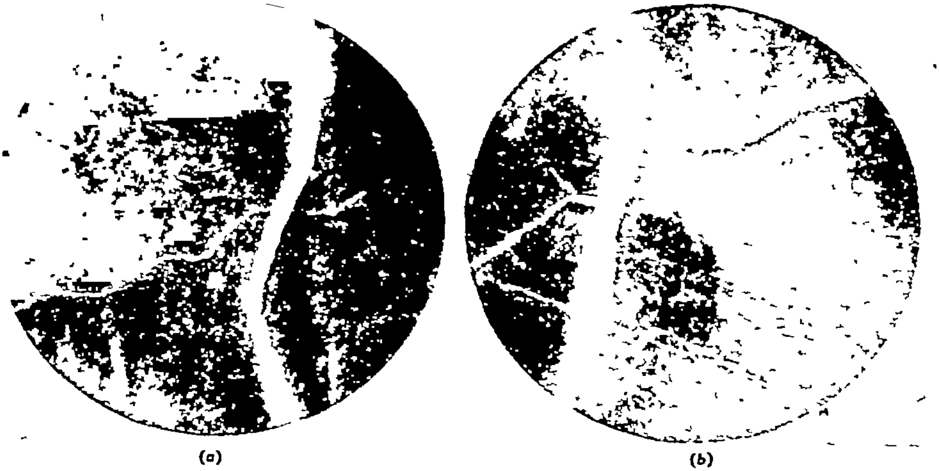
T. D. DAY
M.A., M.D. Camb.
READER IN PATHOLOGY IN THE UNIVERSITY OF LONDON AT ST. THOMAS'S HOSPITAL MEDICAL SCHOOL

A PECULIARITY of interstitial connective tissue which has puzzled histologists for many years is the lack of correlation between its naked-eye and microscopical appearances.

To the naked eye this tissue appears in the form of membranes of various thicknesses. These membranes present considerable obstruction to the spread in the tissues of effusions of blood, inflammatory exudates, and malignant tumours and may therefore be considered to be relatively impermeable to particles of the size of red blood corpuscles. In contrast the microscopical picture of connective tissue, whether derived from stained sections or from the examination of fresh tissue, in no way suggests a membranous structure; connective tissue appears to be composed of a network of fibres with occasional spindle-shaped or stellate cells, the meshes of the net being considerably larger than the particles to which connective tissue is so obviously impermeable.

It was suggested by Flemming [1] that connective tissue is not composed merely of cells and fibres but that these structures are combined into membranes by some sort of cementing substance. More recently Laguesse [2] claimed that he had demonstrated an essentially lamellar arrangement in connective tissue. The observations described here tend to confirm this conception of the structure of connective tissue and thus to bring its microscopical into conformity with its naked-eye appearance.

From a recently killed rat, a thin lamella of connective tissue was excised, moistened with neutral distilled water, and spread out on a glass slide. The corners were drawn out with filter paper until they became dry and adherent, whereupon they were firmly fixed with a drop of melted paraffin wax; meanwhile the main part of the preparation was kept moist. When the corners had become firmly anchored, the preparation was treated with dilute acid at a pH of 3·6, after which a coverslip was applied, and the edges of it were sealed to the slide with paraffin wax.



(a)   (b)

Dark-ground picture of a piece of rat fascia mounted in distilled water: (a) at pH 7·0, showing two collagen bundles; (b) same field after treatment for several minutes at a pH of 3·7. Cobweb-like fibrils have appeared. They have been formed in a tautly stretched membrane of extreme thinness and therefore lie in the same optical plane. (× 600.)

When the thinnest parts of such a preparation were examined microscopically with dark-ground illumination, the spaces between the brilliantly refractile collagen bundles were filled by a moderately dense opacity. Careful examination of this opacity with the highest magnification revealed that it was composed partly of a faint amorphous haze, partly of refractile granules, and partly of exceedingly fine angularly branching fibrils. The smallest collagen and elastic fibrils were embedded in the general opacity like twigs on the surface of a frozen pond. It must be emphasised that even when these structures were freely suspended in the mounting fluid, and not attached to either the slide or the coverslip, they lay in the same optical plane. With the slightest alteration in focus they all disappeared together. A similar effect was produced when the coverslip was gently pressed. The impression given was that of an extremely thin and tautly stretched membrane. In places the tension of the membrane had altered the alignment of the collagen bundles to which it was attached. Elsewhere, where the membrane had become unduly stretched, it had broken up into a system of branching fibrils with attached granules (see figure), the intervening opaque haze having disappeared. Networks formed in this way still tended to lie in one plane and looked like a cobweb. In places where the tension had been even greater the networks broke down into separate fibrils which no longer lay in the optical plane of the remainder and, when the coverslip was pressed, could be made to move independently.

Similar delicate membranes and cobweb-like networks were also observed in preparations treated for several hours in 50–60% ethyl alcohol at neutrality. However produced they seemed to be permanent structures. They did not disappear when the tissue was again mounted in neutral distilled water, nor even after prolonged treatment with 0·001N NaOH; but they disintegrated rapidly in the presence of trypsin.

The range of pH in which the membranes and cobweb-like fibrils were formed was precise. Between pH 3·6 and 3·9 they formed within a few minutes; at pH 4·2 their formation was much slower and incomplete; and at pH 4·6 they did not appear at all.

After fixation these preparations gave negative reactions for fibrin both when stained by phosphotungstic acid hæmatoxylin and by Weigert's method. The appearance of the cobweb fibrils on dark-ground illumination also differed entirely, both in delicacy and mode of arrangement, from that of fibrin.

The irreversible formation of these membrane-like structures within a narrow range of pH strongly suggests that the phenomenon is due to the precipitation of a protein at its iso-electric point; moreover the facility with which the membranes were disintegrated by trypsin seems to indicate that protein plays an essential part in their composition.

Gurevitch et al. (present series)	Jews (Jerusalem)	1913	1730 (*90·4*%)	183 (*9·6*%)

Jewish community in Jerusalem is composed of groups of different origin adds to the interest of this study.

INVESTIGATION AND RESULTS

The material included in the present investigation consists of 940 women attending the prenatal clinics of the Hadassah Medical Organisation, 372 women delivered in the obstetrical department of the Hadassah University Hospital, 214 cases taken at random from among hospital patients and personnel, and 387 women whose obstetric history suggested Rh incompatibility. The results of the investigation showed that 9·6% were Rh-negative. These figures are compared in table I with those found in other racial groups.

To determine the distribution of the Rh antigen among the various Jewish communal groups studied, we have divided our material according to the origin of the patients: (1) Ashkenazim, of European origin; (2) Sephardim, from Mediterranean countries (Egypt, Tunis, Morocco, Greece, Bulgaria, &c.); (3) Yemenites, originating from the Yemen; (4) Kurds and Persians, originating from Northern Iraq and Persia; and (5) combined minor groups of oriental origin (Georgians, Babylonians, Assyrians, and others). The results of these studies are summarised in table II.

From table II it is evident that two groups stand out as having a very small proportion of Rh-negative persons among them—the Yemenite and the Kurdistani-Persian Jews. These groups contrast with the other communal groups, which have a ratio of Rh-negative persons nearer to that found in the white continental races, and it is perhaps significant that these two groups are noted for their segregated way of life, and intermarriage is very rare among them. Their very low proportion of Rh-negative persons is associated with an apparent absence of erythroblastosis fœtalis—out of 310 deliveries of Yemenite Jewesses and 1739 deliveries of Kurdistani-Persian Jewesses in the obstetrical department of this hospital during the last six years there has not been one case of erythroblastosis fœtalis.

TABLE II—RH FINDINGS IN DIFFERENT GROUPS OF JEWS

Group	No. of cases	Rh-positive	Rh-negative
Ashkenazim	1035	921 (*89·0*%)	114 (*11·0*%)
Sephardim	262	231 (*88·2*%)	31 (*11·8*%)
Yemenites..	44	43 (*97·7*%)	1 (*2·3*%)
Kurds and Persians ..	203	200 (*98·5*%)	3 (*1·5*%)
Combined minor groups..	369	335 (*90·8*%)	34 (*9·2*%)

It should be pointed out that our material comprises two clinically distinct groups: the one taken at random—i.e., not selected—and the other selected because the obstetric history suggested Rh incompatibility. The suggestive obstetric history was one in which, after one or more normal deliveries, there were stillbirths, premature deliveries, abortions, &c. Table III shows that the incidence of Rh-negative persons in these two clinically distinct groups among the Ashkenazi Jews was practically the same. This seems to indicate that the incidence of Rh-negative persons plays no important rôle in the general obstetric pathology (stillbirth, abortion, antenatal death, &c.), but it does not lessen the importance of Rh antigen as a decisive factor in hæmolytic disease of the newborn.

DISCUSSION

As pointed out above, hæmolytic disease of the newborn is relatively rare in Palestine. Out of 12,645 deliveries in the obstetrical department of the Rothschild Hadassah University Hospital, there have been 5 cases of erythroblastosis fœtalis and 1 case of congenital anæmia during the past eight years. If we are to assume, on the basis of our findings in 2000 cases, that the ratio of Rh-negative persons in our obstetrical material is about 10%, it means that the total number of Rh-negative women delivered in our department was about 1264. It follows that only 1 of every 210 Rh-negative women has given birth to a child with hæmolytic disease of the newborn.

TABLE III—RH FINDINGS IN ASHKENAZI JEWS

Group	No. of cases	Rh-positive	Rh-negative
Selected ..	483	429 (*88·8*%)	54 (*11·2*%)
Not selected ..	552	492 (*89·1*%)	60 (*10·9*%)

It has already been observed that the ratio of hæmolytic disease of the newborn to Rh-negative mothers is about 1 : 50 (Wiener 1945). Wiener (1946) has suggested that this is due to a constitutional factor, which he has designated "K" and which confers the ability to produce antibodies in response to an incompatible antigen. If Wiener's view is correct, it seems that, besides a relatively low incidence of Rh-negative persons among our material, there is also a reduced incidence of the constitutional factor K.

SUMMARY

Among 1913 Jews of different origin the incidence of Rh-negative persons was found to be 9·6%.

These included 203 Kurdistani-Persian Jews and 44 Yemenite Jews, in whom the incidence of Rh-negative persons was 1·5% and 2·3%.

Among 12,645 deliveries in eight years there were only 6 cases of hæmolytic disease of the newborn, an incidence of 1 in 210 deliveries. Among 2049 deliveries in Kurdistani-Persian and Yemenite Jewesses in six years there was not a single example of hæmolytic disease of the newborn.

The relation between the low incidence of Rh-negative persons and the rarity of hæmolytic disease of the newborn among them is discussed.

except that three months later he still experiences some discomfort in the right side of the pharynx.

Varicella in Contacts.—On Jan. 2, 1946, patient's daughter, aged 13 years, and two days later her brother, aged 4 years, exhibited typical varicella rashes.

The development of varicella by the patient's two children living at home, 14 and 16 days after the father's eruption, strongly supports the diagnosis of zoster. The case is therefore presented as one of zoster of the right glossopharyngeal nerve with probable involvement of the right vagus nerve.

Preliminary Communication

DETECTION OF LATENT GENITAL TUBERCULOSIS BY CULTURE OF MENSTRUAL DISCHARGE

LATENT female genital tuberculosis is commoner than has been hitherto suspected, as shown by endometrial biopsies in cases of primary sterility in women without any clinical symptoms pointing to either general or genital tuberculosis.

Berblinger[1] found only 7·8% of genital tuberculosis in 320 necropsies on women who died of pulmonary tuberculosis. Lackner et al.[2] found the same percentage in necropsies on tuberculous women. The fact, however, that they found tuberculous endometritis in only 1·6% of 125 women with active pulmonary tuberculosis who were submitted to endometrial biopsy is very significant.

This is in contrast with the results obtained by Schockaert and Ferin[3] in Belgium, Sutherland[4] in England, and Rabau et al.[5] in Palestine, who found tuberculous endometritis in an average of 5% of women with primary sterility.

A still higher incidence of tuberculous endometritis was found by me[6] in sterile women in whom salpingography showed a tubal occlusion.

Hitherto endometrial biopsy has been considered the most reliable criterion of genital tuberculosis in a woman; but it can give a positive result only when tuberculosis has already reached not merely the endometrium but also the particular portion of it removed for scrutiny. Further, the manipulation with instruments of women suspected of genital tuberculosis is not devoid of danger. In 5 of our patients with tuberculous endometritis curetting was followed by severe pelvic peritonitis.

Nor have the various specific and aspecific tests contributed much to the diagnosis of latent genital tuberculosis. The erythrocyte-sedimentation rate was normal in all cases of tuberculous endometritis. The intradermal tuberculin reaction (Mantoux) was in most cases positive; but this does not prove much in adults and certainly does not indicate the structures involved. For the same reason we have abstained from using the complement-fixation test.

Theoretical and practical considerations led us to try to isolate the *Mycobacterium tuberculosis* in the menstrual discharge by means of specific culture media.

TECHNIQUE

The menstrual discharge is a mixture of blood, mucus, and parts of the endometrium. The blood is found in the vagina partly in a non-coagulated condition. We removed as much material as possible from the fornix and the os with a vaginal speculum and transferred it to a sterile test-tube containing 1 ml. of our anticoagulant solution, using Petragnani's specific culture medium. The women were told to report the first or second day of the menses. We consider it imperative to repeat the test at least thrice in the same patient, because often we obtained positive results only after one or two negative tests. Only positive tests are to be considered; negative results do not exclude genital tuberculosis.

MATERIAL AND RESULTS

The menstrual discharges of 80 women with primary sterility were examined. Among them were 10 women in whom endometrial tuberculosis had been found before this test, and in 2 others genital tuberculosis was clinically suspected. Of 140 tests made in these 80 women, in 9 cultures colonies of *M. tuberculosis* were found, whereas 19 others showed non-pathogenic acid-fast bacilli.* In 3 cases of cultures containing *M. tuberculosis* the results were confirmed by animal tests. By the same methods the menstrual blood of 30 healthy women who previously had given birth to at least one child was examined as a control, and in only 1 case did non-pathogenic acid-fast bacilli grow. The 9 positive cultures came from 6 women whose histories follow:

Case 1.—A woman of 34 with eight years' primary sterility. Five years ago we had found that she had tuberculous endometritis. Manual examination of genitalia negative. Mantoux positive. Radiography of lungs normal. For the last three years she had had tuberculosis of the kidneys.

Menstrual blood on culture gave *M. tuberculosis* in 4 tests made in 4 consecutive menses, whereas cultures from peripheral blood were negative. Animal tests were positive.

Case 2.—A woman of 28 with five years' sterile marriage. Result of endometrial biopsy suggested tuberculous endometritis. Bimanual examination of genitalia negative. Erythrocyte-sedimentation rate normal. Lungs normal.

Cultures of menstrual discharge gave negative results twice, but the third time gave *M. tuberculosis.* Animal tests positive.

Case 3.—A woman of 32. Bimanual examination revealed a tumour the size of an average apple in the region of the right adnexa, probably inflammatory in origin. Cultures gave at first a negative result; the second test, however, was positive.

Case 4.—A woman with three years' primary sterility. Endometrial biopsy showed no sign of tuberculosis. Cultures of menstrual discharge were positive for tubercle bacilli. Culture of peripheral blood negative.

Cases 5 *and* 6.—Two women with primary sterility of one or two years' duration. No genital or other tuberculosis suspected. Cultures of their menstrual discharges grew *M. tuberculosis.*

All the bacteriological tests were made in the central laboratories of the Kupath Cholim, Tel Aviv.

DISCUSSION

The possibility of cultivating *M. tuberculosis* from menstrual discharge on specific culture media is of great practical importance. It is not difficult to distinguish morphologically *M. tuberculosis* from non-pathogenic acid-fast bacilli. Even the macroscopical appearances

GLOSSOPHARYNGEAL ZOSTER

FOLLOWED BY VARICELLA IN TWO CONTACTS

FREDERICK J. WRIGHT
M.D. Camb., M.R.C.P., D.T.M. & H
MEDICAL SPECIALIST, COLONIAL MEDICAL SERVICE

A CASE of zoster in the distribution of the glossopharyngeal nerve is reported here. Wilson (1940) reports a similar case and states that very little seems to be known of zoster in this distribution. Hunt (1910), however, cites a case reported by Chauveau in 1901 in which the vesicles were limited to the zone supplied by this nerve, and he lists, under the heading "herpes pharyngis," eighteen published cases of which at least five appear to refer to zoster, one (Lermoyez and Barozzi 1897) being bilateral. All of these cases may not have been glossopharyngeal in origin, for ipsilateral vesicles on the hard and soft palates may appear in geniculate zoster, owing, it is thought, to involvement of the greater superficial petrosal nerve (Wakeley and Mulvany 1939). The only reference I can find in the *Quarterly Cumulative Index Medicus* since 1920 to glossopharyngeal zoster, unassociated with facial paralysis, is a case reported by Gounelle and Warter (1934). Glossopharyngeal zoster in combination with geniculate zoster, characterised by facial paralysis besides the vesicular eruption, is described by Hunt (1910), McKenzie (1915, quoted by O'Neill 1945), Neve (1919), Dennis (1925, quoted by Watson 1941), Jacques (1931), Nattkemper (1932), Rabbiner (1938), Baldenweck and Degorce (1939), Watson (1941), and Negus and Crabtree (1943).

When the vagus nerve is involved, besides laryngeal vesicles, persistent nausea and vomiting are conspicuous features; in Watson's (1941) case they persisted five weeks. These symptoms were also prominent and persistent in the present case, but there were no laryngeal symptoms.

The ganglia connected with the following cranial nerves —viz., the 5th (semilunar ganglion), 7th and 8th (genicular ganglion), 9th (superior and petrous ganglia), and 10th (jugular ganglion and ganglion nodosum)— are developed from the neural crest and are thus homologous with the spinal posterior root ganglia. It therefore seems probable that the superior and petrous ganglia are primarily involved in glossopharyngeal zoster, and in the present case the jugular ganglion and the ganglion nodosum may also have been involved.

Doubt has been cast on the rôle of the genicular ganglion in the Ramsay Hunt syndrome of geniculate zoster. Denny-Brown et al. (1944) have reviewed the scanty histological reports and contend that characteristic lesions have not been demonstrated in the genicular ganglion. Though it must be admitted that lesions round the ear in conjunction with facial paralysis may result from various combinations of zoster of cranial nerves and from involvement of the second and third cervical ganglia (zoster occipitocollaris), the histological evidence is so scanty that it seems to me that O'Neill (1945) tends unnecessarily to belittle the probable rôle of the genicular ganglion. Nevertheless, since zoster may spread beyond the confines of the ganglia and sensory neurones and involve spinal motor tracts (Taterka and O'Sullivan 1943) and may even cause encephalitis (Schiff and Brain 1930), and since aberrant vesicles and generalised vesicular rashes may develop, it is impossible to demarcate with certainty the sensory zone or motor connexions of a single ganglion from a solitary attack of zoster.

The eruption in glossopharyngeal zoster is seen as an ipsilateral involvement of the pharynx, tonsillar fossa, faucial pillars, and soft palate. Hunt (1910) considered that the posterior portion of the tympanum might also be involved, and this was described by Chauveau in 1901. I did not investigate this point carefully, but the lack of pain in the ear, after the eruption developed, suggests that the tympanum was not affected, and Wilson (1940) and Neve (1919) state that the tympanum was unaffected in their cases.

CASE-RECORD

A British male post-office official in Kenya, aged 47, had had varicella, with his sisters, at the age of 10 years.

The only other features of note in his previous history were recurrent troubles with the left parotid gland from 1933, culminating, in November, 1944, in the drainage, through the parotid duct, of a cystocele of the left parotid gland.

On Dec. 14, 1945, he began to have pain in the throat and, to a less extent, in the right ear for five days. During the first four days he continued at work.

On the sixth day I was called to visit him and found the temperature 100°F. There was a little cerumen in the right external auditory meatus and, so far as could be seen, only slight congestion of the tympanum.

In the pharynx there were several ovoid ulcers, about 0·8 cm. × 0·2 cm., on the posterior pharyngeal wall to the right of the midline.

A direct smear from a throat swab did not reveal any pathogens, and on culture only *Neisseria catarrhalis* and pneumococci were grown. Patient was given benzylsulphanilamide ('Proseptasine') 1 g. four-hourly. Next day the condition was unchanged, and another throat swab gave identical results.

Next day (Dec. 21), the throat being still more painful and the patient vomiting, he was admitted to the European Hospital, Nairobi, under my care. Temperature 100°F, pulse-rate 88. Besides the ulcers on the posterior pharyngeal wall, there was now a cluster of superficial ulcers of various shapes on the right half of the soft palate, each ulcer being surrounded by a linear erythematous zone.

These ulcers were arranged in groups, the most anterior reaching nearly to the junction between the soft and hard palates. Except one rather large oval ulcer, whose long axis was exactly in the midline of the posterior pharyngeal wall, all the ulcers were situated to the right of the midline and were scattered on the posterior pharyngeal wall, right tonsillar fossa, faucial pillars, and soft palate.

Next day other spots were noted: one on the nose in the midline, most of them on the right side of the chest and right arm, but a few to the left of the midline. One of these I saw in the vesicular stage; the others had already formed superficial raw areas.

The ulcers in the throat were extremely painful, and nausea persisted. Taste was not tested. The right ear had ceased to be painful, and the tympanum was not re-examined.

No lesions were seen on the protruded tongue, but patient said the back of the tongue felt sore but that the remainder of the tongue felt normal and appreciated taste normally. There were no lesions on the hard palate, buccal mucosa, or right pinna.

The preceding pain, the pyrexia, and the character and distribution of the lesions led me to diagnose glossopharyngeal zoster with some scattered aberrant lesions on the trunk, nose, and limbs. The remaining cranial nerves (with the probable exception of the vagus) were unaffected; no motor changes or other physical abnormalities were detected. The larynx was not examined.

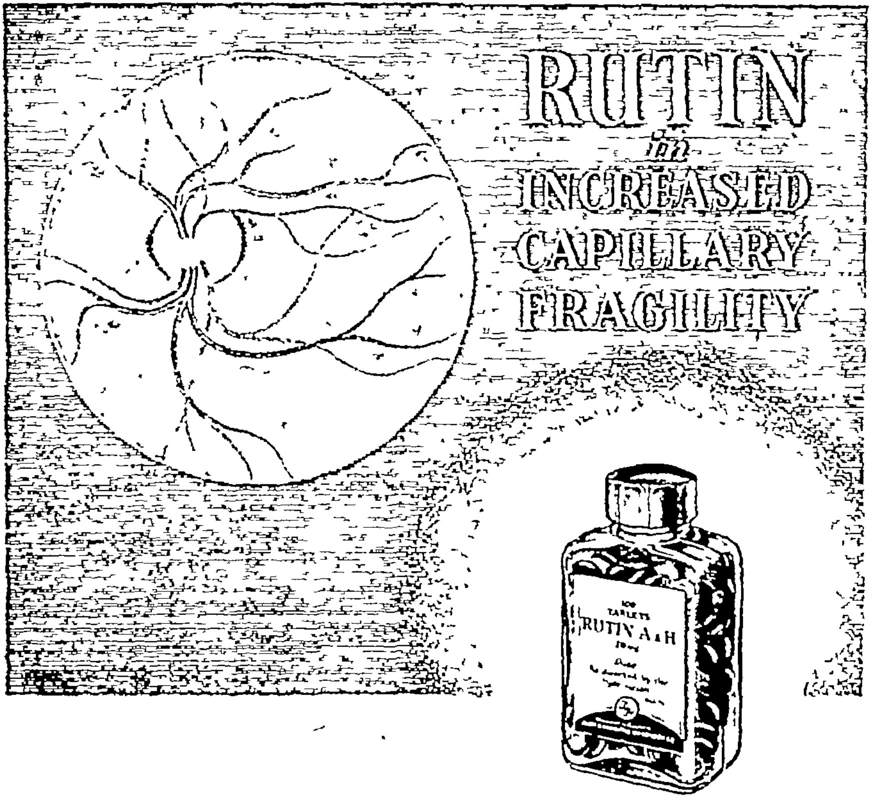
Temperature was 100°F at night on the 21st and 22nd, 99·2°F on the 23rd, and normal on the mornings of the 23rd and 24th. On the 21st there were 9100 leucocytes per c.mm. (neutrophils 77%, lymphocytes 20%, mononuclears 3%).

After patient's admission to hospital no more sulphonamides were administered, but he was given aspirin gargles, nicotinic acid, and phenobarbitone, and the ulcers were swabbed with 1% cocaine, without much relief being obtained. I regret that I did not administer pituitrin.

On the 24th patient felt somewhat improved and went home for Christmas. Nausea and frequent vomiting persisted.

I re-examined him on the 29th and found the pharynx practically normal, only a few injected spots being discernible. The bowels were open normally, but nausea and vomiting continued. These symptoms suggested involvement of the right vagus nerve. Radiography after a barium meal on Jan. 7, 1946, gave no evidence of an organic lesion in the stomach or duodenum.

Nausea, with occasional vomiting, persisted a further ten days, since when patient has been in normal health.



Increased capillary fragility, with its attendant risk of submucous or subcutaneous hæmorrhage, is the primary indication for the therapeutic use of Rutin, a flavonol glycoside credited with the physiological properties hitherto ascribed to vitamin P.

Clinical trials, some of which were summarised in the *British Medical Journal*, May 31st, 1947, page 771, suggest that Rutin may be an important factor in the prevention of retinal hæmorrhage in patients with hypertension, and in controlling bleeding in hereditary telangiectasia.

Rutin A & H is suggested for administration in hæmorrhagic conditions due to increased capillary permeability associated with hypertension, nutritional deficiency or toxic effects of drugs.

Rutin Tablets, each containing 20 mg., are available in bottles of 100.

of the colonies are completely different. In doubtful cases, however, it is advisable to inoculate the material from the cultures into animals to test their pathogenicity.

In cases where genital tuberculosis is clinically suspected the culture of menstrual discharge is the only safe method of establishing the diagnosis. Further, it is advisable to examine menstrual discharge at least thrice in cases of primary sterility before engaging in intra-uterine intervention (insufflation, salpingography, endometrial biopsy).

The presence of *M. tuberculosis* in the menstrual blood is, in all probability, not due to a bacteræmia. In all those cases in which the peripheral blood was examined no *M. tuberculosis* were found, though the menstrual blood was positive.

It is not yet known how far these women are dangerous to their environment owing to the discharge of *M. tuberculosis* in the menstrual blood. Though the husbands of these women do not show any inoculation of tuberculosis on their genitalia, such women are advised to take precautions against the possibility of disseminating *M. tuberculosis* in their menstrual blood.

SUMMARY

The menstrual discharges of 80 women with primary sterility were examined by means of specific culture media for the presence of *M. tuberculosis*.

Out of 140 tests there were 9 positive findings in 6 patients.

In 19 cultures only non-pathogenic acid-fast bacilli grew.

I wish to thank Dr. E. L. Bregman, director of the laboratories, and his collaborators, Miss Miriam Porechodnik and Mr. N. Vigodsky, for their inestimable help; and Professor Klopstock for valuable suggestions, and providing facilities for the animal tests.

Reviews of Books

Obstetrics and Gynæcology

A Revision Course for Practitioners. C. SCOTT RUSSELL, M.A., M.B., F.R.C.S.E., M.R.C.O.G., assistant director, department of obstetrics and gynæcology, University of Manchester. London: Oxford University Press. 1947. Pp. 211. 13*s.* 6*d.*

THIS is a book of truly remarkable brevity, which within its small compass manages to say a great deal, all of it orthodox and sound. It cannot, however, be regarded as more than a refresher. The subject of gynæcology is literally written off in under 50 pages, whereas X-ray pelvimetry in disproportion is given disproportionate prominence, considering that this is a luxury which the average practitioner must usually do without. It is hinted, however, that this book is for the doctor whose life in the Armed Forces has sheltered him, for a while, from the wrath of the P.P.H. to come; and its avowed purpose is to stimulate him to renew his acquaintance with the subject. Within these limitations it is admirable.

The Doctor and the Difficult Adult

WILLIAM MOODIE, M.D., F.R.C.P., D.P.M., physician, department of psychiatry, University College Hospital. London: Cassell. 1947. Pp. 296. 15*s.*

Dr. Moodie has exceptional knowledge of the "difficult" of all ages. Here he deals with those who have the years but not the discretion of the fully grown. As might be expected, his book is simply written, wise, and full of common sense.

The writer of a non-technical book dealing largely with the neuroses is, however, beset by a special difficulty: any simplified account of psychotherapy is apt to leave the reader asking "Is that all there is to it?" Even Dr. Moodie, with all his skill, tends to leave the impression that good will and common sense are not only necessary but also sufficient.

He may be said to belong to the English eclectic school. Eclectic, because he acknowledges no allegiance to any one predecessor; English, because of his empiricism, his freedom from general principles or a-priori concepts. English, too, in the convention that normality implies understatement—indeed, denial—of emotion, feeling, æsthetic sensibility, or intellectual probing. His philistine values sometimes shock in several ways at once:

> "The law in English-speaking countries still looks upon homosexual acts as illegal and punishable. . . . There can be no doubt that the law in England is right."
>
> "The usual religious teaching which means Bible study by children who cannot understand it and learning the Catechism by memory under the supervision of uninterested teachers . . . would usually be better left alone, and the same applies to sex teaching."

It is all the more impressive that he comes out as an uncompromising opponent of corporal punishment. And here he takes the trouble to present us with evidence, not prejudice.

The chapter on the approach to the difficult patient is particularly good, giving some of the details and fine points which are the harvest of psychiatric experience, and which form no part of the equipment of the well-intentioned but untrained.

Cancer: Diagnosis, Treatment and Prognosis

LAUREN V. ACKERMAN, M.D., pathologist to the Ellis Fischel State Cancer Hospital; JUAN A. DEL REGATO, M.D., radiotherapist to the hospital. London: H Kimpton. 1947. Pp. 1115. £5.

THE authors have provided a satisfactory guide, though they have not altogether overcome the difficulty of giving an adequate outline of treatment without entering into detail. Special efforts are being made in the United States to ensure early diagnosis. Michael B. Shimkin summarises cancer research, the histological studies of the early oncologists, animal tumours, carcinogenesis, the rôle of heredity, and the effects of œstrogens and other hormones, rounding off with a section on cancer theories. Biopsy methods are discussed, and there is a short general chapter on surgery. The account of radiotherapy wastes space on elementary radiation physics and technical aspects of X-ray therapy which have had to be so condensed as to have little value. Cancer of the skin is well described and illustrated, and there are useful notes on ætiology and on the lesions which simulate skin cancer. The section on treatment of cancer of the mouth and tongue is poor, the diagram of radium implantation of the tongue showing an old-fashioned type of implant. The discussion of cancer of the larynx shows the influence of the French school, and the descriptions of the various cancers found in the alimentary tract, from œsophagus to rectum, should be very useful to senior students. The authors insist on the curability of cancer of the female generative organs. The book is completed by sections on tumours of bone, sarcoma of the soft tissues, and Hodgkin's disease and the leukæmias.

Well planned and readable, the book will be serviceable to all cancer students, though radium is not given its true place as the most effective weapon we have at present against many of the accessible cancers. The important work of the British school on radium dosage, and the results obtained, are almost ignored, which must inevitably bias the choice of treatment in America.

Manual of Physical Diagnosis (3rd ed. Chicago: Year Book Publishers; London: H. K. Lewis. 1947. Pp. 351. 27*s.* 6*d.*).—It is only meet that a steady stream of books on physical diagnosis should be issuing from the home of laboratory medicine. The special feature of this one is that it is concerned mainly with the respiratory and circulatory systems, although there are also brief sections dealing with the abdomen, the genitalia, and the central nervous system. Dr. Ellis B. Freilich, Dr. George C. Coe, and Dr. Joseph Freilich have made a laudable attempt to correlate physical signs and pathology, and the book can be safely recommended to the student as an introduction to clinical medicine.

THE LANCET

LONDON: SATURDAY, DEC. 27, 1947

Health at the University

A CONFERENCE held last summer[1] at the Institute of Social Medicine in Oxford, and attended by delegates from 15 universities, 11 medical schools, and various other important bodies, gave the academic world a signal for action. It has long been recognised that welfare provisions in British universities are in many ways inadequate, and that the health and sickness of students have had too little attention. Abroad, organised health examinations, including radiography of the chest, were instituted in Munich as early as 1927 and later extended through the German universities; in the United States the leading universities have set an example in the same way; and in 1938 an international university conference devoted five days to a discussion in which 50 representatives from 15 nations advocated compulsory health examination Both the Goodenough Committee and the Royal College of Physicians committee on social and preventive medicine have strongly recommended the universities to establish student health services, and the students themselves—through the National Union of Students, the British Medical Students Association, and other groups—have sent out questionaries and published thoughtful memoranda on their own needs Of recent years a few British universities and several medical schools have started partial services; but a fully operative service, making proper provision for periodic health examination and care in sickness, has yet to be announced. While memoranda have accumulated, and a few pioneer undertakings have been launched, the governing bodies of all but a few universities have remained largely inactive: they have had other pressing responsibilities, accentuated by war and its sequelæ. Now, however, there are signs of awakening interest, and the inauguration of the National Health Service (though in its early phases it will be more concerned with sickness than with health) should provide an occasion for new thought and concerted enterprise.

With the costs of illness covered, those who have to provide for the young will increasingly concentrate on earlier detection of defects and on the prevention of any form of disability; and the success of child-welfare centres and school medical services fully justifies extension of interest to the next age-group. The university student is, after all, still in a stage of growth and development: like the youthful entrant to industry, for whom special welfare measures are now required, he is exposed to new hazards on leaving home and school, and for medical students in particular these include exposure to tuberculosis and other infections Furthermore, the undergraduate is at a stage of his educational career when the contribution of health to the evolution of the "whole man" can be usefully emphasised and related to the general academic culture. Nowadays too many of those admitted to universities on the score of scholarship are found to be of poor physique and liable to break down under the stress of a curriculum ill adjusted in its mental and physical demands. Surely the time has come to recognise that the health of this large body of young and partially selected adults, from whose ranks will be drawn a high proportion of the leaders and teachers of the future, matters at least as much as the health of recruits to the Armed Forces

This week we publish papers by physicians concerned in various ways with student health at universities of widely differing character and tradition. Dr. PARNELL, of Oxford, describes the findings in a group of students presenting themselves voluntarily for a health examination, and refers to the need of many of them for simple psychological help. Dr. MACKLIN, of Aberdeen, presents the case for a comprehensive service and reviews organisation, staffing, and costs. He thinks that the same doctor should be responsible for health and sickness, and that he should have beds for investigation and for the treatment of minor illness. Dr. BOLTON, of Birmingham, develops the interesting theme of compulsory physical education during the first undergraduate year, claiming a place for it in the curriculum and emphasising the social as well as the physiological benefits of a well-organised system allowing the student plenty of choice. No doubt he is right in saying that "the native resentment of compulsion is, after all, something of a bogy." At British universities compulsory medical examination has never been suggested as a means of selection or exclusion; it takes place after entry and is intended to give the student a better prospect of enjoying and profiting by his scholastic course and of avoiding interruptions by sickness Again, in favour of making physical education compulsory Dr. BOLTON can fairly plead that mental education is already based on compulsion; attendance at lectures has long been obligatory, and compulsory attendance on the field or in the gymnasium he regards as a corollary, designed to bring physiological and social balance into a system which has put too much emphasis on midnight oil and competitive examinations. If it is really true, as preliminary surveys suggest, that some 80% of university students take no regular part in games or other health-giving outdoor activity, it is certainly time that the conditions and purposes of a modern university training were reviewed. In the hands of some of its Continental exponents the cult of physical fitness has shown an unattractive side; and most of us like to think of a university as a place where undergraduates enjoy a great deal of freedom—especially perhaps, to make mistakes. There must, however, be many remedies besides compulsion applicable to institutions where a majority of young people do not follow their natural bent towards athletic pursuits, and undoubtedly a great deal more could usefully be done for the average student—even if the aim is simply to make him healthy enough to be unaware of his health. There will be warm support for our colleagues who take up this important new work.

Meeting Deficiency . . . . .

CORPUS LUTEUM HORMONE

'ORALUTON' (Ethisterone), although not a complete substitute for progesterone, is useful in correcting progestational failure, its great advantage being convenience of oral administration.

Cases of habitual and threatened abortion, sterility, spasmodic dysmenorrhœa, adolescent and menopausal hæmorrhage and pre-menstrual tension, frequently respond to treatment with 'Oraluton.'

ANAHÆMIN B.D.H.

Anahæmin B.D.H. has become established as a standard product for the treatment of pernicious anæmia. Clinical use during more than a decade has provided abundant evidence of its erythropoietic potency, its comparative freedom from allergenic properties and its efficacy in preventing and arresting subacute combined degeneration of the cord.

Effective doses of Anahæmin B.D.H. are small in volume and, in maintenance, satisfactory doses may be given at relatively infrequent intervals.

Anahæmin B.D.H. produces an improvement in the patient's subjective condition, even before an increase in the R.B.C. can be detected. This property has been utilised in the treatment of the debility caused by severe infections and that resulting from major surgical procedures. Each batch of Anahæmin B.D.H. is clinically tested before issue.

and an amount sufficient to cause toxic reactions (particularly those related to thecal or meningeal irritation); and the possible significance of the lymphocyte-count of the cerebrospinal fluid in prognosis Streptomycin is clearly of short-term radical benefit in some cases of tuberculous meningitis, though the various factors involved and the best schedule of administration have yet to be worked out. Much will be expected on these points from the current Medical Research Council trials

The discovery that tuberculosis can after all be affected by systemic drugs may lead enthusiasts to disregard the strict criteria for assessing the efficacy of treatment ably set out by HINSHAW and FELDMAN.[10] There are already signs that the improvement noted in a hotch-potch of cases, without untreated controls, will be ascribed to some new drug, without regard to the possibility of spontaneous remission If this happens the pre-streptomycin story of faded hopes will be repeated It took but a few months of enterprise to introduce tuberculin and 'Sanocrysin' into treatment on a world scale, but more than a decade of scientific slogging to evict them. With streptomycin we have the impressive results in meningitis and miliary tuberculosis to justify the setting up of a limited public service by the Ministry of Health on the advice of the Medical Research Council. But the indiscriminate use of the drug in every type of tuberculosis, which commercial vigour has stimulated in the U.S.A., must be guarded against. Apart from risk to the patient of his tubercle bacilli becoming streptomycin-resistant, there is the wider public-health danger of new cases arising in which the strain is primarily resistant—for example, in infants infected by mothers treated with streptomycin. So the M.R.C. has the unenviable responsibility, not only of assessing the value of the antibiotic and deciding on the best schemes of dosage in various forms of tuberculosis, but also of advising how it should be distributed for public use in appropriate conditions only. While British production is in the pilot stage the council is unlikely to be hustled.

Fibrocystic Disease of the Pancreas

INFANTS who fail to thrive and eventually succumb from a combination of diarrhœa and respiratory infection are sadly familiar in practice. The necropsy usually discloses no convincing cause of death, and doubt remains as to which of the two main symptoms was primary or whether both were secondary to some other fundamental disturbance of nutrition. It now appears that in at least a considerable proportion of these cases there are widespread pathological changes in the pancreas which interfere with the secretion of pancreatic juice and thus impair digestion. Other changes in the body may be secondary to malabsorption of essential foods and vitamins. The principal necropsy finding in the pancreas is dilatation of the acini and ductules from blockage of the lumen with tenacious inspissated material; and the surrounding tissue undergoes pressure atrophy and progressive fibrosis The condition has been named "fibrocystic disease of the pancreas," but there is no true cyst formation, and the fibrous tissue which develops is not prominent in early cases and must be considered secondary. These changes are present at birth and are progressive. There is no evidence of infection and the islet tissue is intact. The main pancreatic duct is normal, and the few cases in which atresia has been reported probably represent a separate condition with somewhat similar clinical effects. According to HOWARD[1] there is a fairly high familial incidence. Chronic suppurative inflammatory changes in the lungs are constantly found in those infants who survive for more than a few weeks; these consist of varying degrees of purulent bronchitis, bronchiectasis, or bronchiolectasis. The respiratory passages are obstructed with tenacious mucoid or mucopurulent material, and the walls are infiltrated with inflammatory cells. Fibrosis follows in those who survive. Keratinising squamous metaplasia is sometimes present in the trachea and bronchi, and occasionally in other organs. Fatty changes in the liver are a common finding.

Isolated instances of this pancreatic disorder, encountered post mortem, have been reported for some years; but its association with symptoms and signs during life was not appreciated and its frequency was quite unsuspected until ANDERSEN[2] drew attention to it in 1938. Her paper was closely followed by three others,[3] each reporting a considerable series of cases, and there have since been numerous reports. There are several reasons for this delay in identifying what now seems to be a definite clinical and pathological entity. In the first place, pathologists did not recognise the condition because, despite the striking microscopical changes, there is usually little to be seen with the naked eye; and they had not been accustomed to making routine sections of the pancreas in infants or young children who had apparently died of respiratory disease. However, with increasing awareness and suspicion, the incidence has been established at about 3% of all infants who come to necropsy[4]; though in one series[5] the incidence was as high as 12%. Clinically, the condition was not recognised because of its similarity to other disorders, particularly respiratory and gastro-intestinal infections in infants and cœliac disease in older children. Symptoms usually appear soon after birth, and infants may die within a few days with intestinal obstruction due to meconium ileus, which is believed to result from the lack of pancreatic enzymes. In other cases symptoms do not develop until later in childhood. Manifestations may be divided into three main groups: gastro-intestinal, respiratory, and nutritional. Digestion is impaired through lack of trypsin, amylase, and lipase; the stools, which are at first loose, become pale and bulky when solid foods are given. Cough develops early and becomes increasingly troublesome; scattered physical signs may be found in the chest, but there is no evidence of frank consolidation. In infancy, X-ray examination is not likely to show more than increased hilar shadows and basal markings; but later on, if the child survives, there will be patchy areas of opacity from consolidation, collapse, and emphysema. The general picture

Three Drugs against Tuberculosis

AMONG the bacterial infections which have hitherto proved resistant to chemotherapy, pulmonary tuberculosis stands out as the main killing disease affecting the productive groups of the population. Hence the keen public interest taken in any agent found to be active against *Mycobacterium tuberculosis*. In his Mitchell lecture last year, HART [1] divided these agents into purely synthetic substances with no known counterpart in nature; synthetic compounds related to some natural substance which has served as starting-point of the series; and substances of biological origin. Clinical trials of a representative of each of these three categories have been reported within the past few weeks.

'Sulphetrone,' a promin-like substance, was synthetically prepared in 1936, but its antituberculous properties were not recognised until 1941. It is more soluble in water and considerably less toxic than many other sulphones. It exerts a moderately suppressive effect on experimental tuberculosis in guineapigs, and this effect is enhanced by synergistic action when the drug is used in conjunction with streptomycin. Last week MADIGAN and his colleagues [2] reported 6 cases treated with sulphetrone by mouth and streptomycin parenterally, and 11 cases given streptomycin alone. Owing to the small numbers, the variety of clinical types, and the absence of controls, the results are difficult to assess and comparison between the two groups is open to doubt. In both, temporary regression seems to have been produced, particularly in miliary tuberculosis, but relapses have tended to follow later, sometimes associated with the development of streptomycin-resistant strains of the tubercle bacillus. Nevertheless, the experimental evidence of synergism between sulphetrone and streptomycin, coupled with the possibility of maintaining reasonable blood-levels of sulphetrone in man safely for long periods, suggests that this combination should be tried in larger and more homogeneous series of selected types of disease, especially acute miliary and meningeal tuberculosis. This preliminary trial makes it unlikely that the onset of streptomycin-resistance can be retarded or prevented by the coincident use of sulphetrone, for increased resistance was found in strains isolated from patients after three months' treatment with both drugs together.

The introduction of *para*-aminosalicylic acid (P.A.S.) by LEHMANN [3] arose from BERNHEIM's observations that the addition of benzoic and salicylic acids increased the oxygen uptake of washed suspensions of tubercle bacilli; this suggested that substituted similar compounds might interfere with the normal oxidations of the bacilli and so inhibit growth. The Swedish workers found P.A.S. strongly toxic to guineapigs, but FELDMAN and others [4] at the Mayo Clinic demonstrated considerable suppression of experimental tuberculosis in these animals. Owing to the difficulties of manufacture and the large doses required, P.A.S. has been scarce, but about 100 cases of various types of clinical tuberculosis have been treated with it in Sweden.[5] The drug was given mainly by mouth and no serious toxic effects were noted. The reasons for crediting the drug with the improvements noted were not strong, and acute miliary and meningeal tuberculosis were unaffected. The 19 pulmonary cases, 13 of them complicated by other lesions, treated with this drug at Grove Park Hospital and lately reported by DEMPSEY and LOGG,[6] also showed a suggestive though not convincing response.

Recent reports on streptomycin confirm its clinical promise in some tuberculous conditions. The preliminary review [7] of the investigation on which the United States Veterans Administration and Army and Navy have been engaged since June, 1946, covers 543 patients, including 245 pulmonary and 84 miliary and meningeal cases who had finished treatment or died. This account should be taken in conjunction with the recommendations of the American Trudeau Society,[8] published simultaneously. Outstanding findings are the regressive effects of streptomycin in acute miliary tuberculosis and tuberculous meningitis, already demonstrated by the Medical Research Council trial in this country. Striking benefit was also noted in laryngeal and *tracheobronchial ulcerations, and in cutaneous sinuses*, conditions which can be directly observed. Regarding pulmonary tuberculosis the provisional verdict is much more cautious. As would be expected, chronic fibrocaseous disease is little affected and chronic cavities rarely close. The exudative elements of pulmonary tuberculosis, including bronchopneumonia, seemed to run a more favourable course, compared with past clinical experience—not a very reliable guide—but the improvement was most definite during the first three months of therapy; relapses sometimes occurred during the latter part of the course and were noted in a fifth of the cases after the cessation of treatment; seldom, moreover, did all exudative lesions resolve in a given patient. The two bugbears of streptomycin are acquired resistance and chronic toxicity (particularly affecting the labyrinth), and on account of these the American workers advise against its use in minimal or early pulmonary tuberculosis with favourable prognosis, or where conventional therapy seems likely to be effective. Thus in pulmonary tuberculosis streptomycin must be looked on as an adjunct to the well-established methods of treatment. In genito-urinary and bone and joint tuberculosis the limited trials have so far yielded inconclusive results. The broad conclusions of these American reports are reinforced by the preliminary results in tuberculous meningitis treated at the Sick Children's Hospital, Paris.[9] Of the 118 children receiving streptomycin, 46 who have been treated for from two to ten months are "behaving like normal beings," though their ultimate fate is, of course, an open question and the number given in the detailed table (of later date than the text) as "well" or "condition good" is only 25. The experience in Paris emphasises the vital factor of early diagnosis (and the value of retinal examination); the importance of steering between inadequate dosage took the swabs, the conditions were the same. This time, the immunised yielded 2 carriers and the non-immunised none. With the exception of one avirulent mitis strain, all the *C. diphtheriæ* recovered were of the *intermedius* type (the cause of the few cases of clinical diphtheria in the city hospital). Soothill points out that, though still not statistically significant, these figures are comparable with those reported by the L.C.C. Public Health Department.[4] A parallel investigation in June, 1944, among 200 adults, mainly factory workers, drawn from widely separated parts of Norwich produced completely negative results.

Though gratified as an epidemiologist, Soothill is still unsatisfied as a statistician, and he asks for more investigations of carrier-rates among immunes and non-immunes, account being taken not only of the state of immunity but also of the degree of exposure. It is useless, as he says, to compare closed with open communities. In the former immunisation may not prevent a temporary rise in the carrier-rate if diphtheria is endemic,[5] but in communities where immunisation is extended to the greater part of the most susceptible population—the pre-school and school children—McKinnon [6] points out that there is a fall in the incidence of clinical cases and carriers and that both classes in the end virtually disappear. Thus in Toronto (population 650,000) in 1926, a pre-immunisation year, there were 1098 cases of diphtheria with 90 deaths, and 13,231 swabs were examined of which 2564 were positive. In 1936, when 104,449 persons were known to have been immunised, there were 48 cases of diphtheria with 2 deaths, and 4307 swabs were examined of which 80 were positive. In 1937, surveys of 1774 school-children in Montreal yielded only 2 carriers. The figures for Canadian cities in 1947, ten years later, when they are published, should be conclusive enough to satisfy the most sceptical.

AMINO-ACIDS TO INCREASE PERIPHERAL BLOOD

PROTEINS by virtue of their specific dynamic action are well known to increase heat-production in the body, but there is some doubt whether this increase is accompanied by a rise in the skin temperature of the extremities.[7] The specific dynamic action of proteins mainly depends on the presence of a few amino-acids, particularly glycine, alanine, phenylalanine, and tyrosine. Gubner and his colleagues [8] have given glycine in doses of 20 g. by mouth, dissolved in 200–300 ml. of milk, to 25 subjects, some of whom had peripheral vascular disease. In 18 of these the average maximal rise in oxygen consumption above the basal level was 18·4%, but there was a considerable variation in the individual figures and in 4 subjects there was no significant rise in consumption. Skin temperatures were measured in 11 normal people and in 4 patients with peripheral vascular disease, and the glycine was found to raise the temperature of toes and fingers in 3 out of the 4 patients. The rise was greatest in the toes, and the normals showed a rise of 4°C, compared with 2·3°C in the patients. In 6 cases a posterior tibial nerve block was found to have much the same effect as glycine on skin temperature. Glycine produced a significantly greater rise of skin temperature than the ingestion of alcohol. Oscillometric pulsation in the calf was increased after the ingestion of glycine in 8 out of the 11 normal subjects, but in none of the patients with peripheral vascular disease, even though 2 of the patients had significant rises in skin temperature. Blood-flow to the extremities, as measured by venous occlusion plethysmography, was increased by glycine, the average rise being 62% in 4 normal subjects, and 30·5% in 4 patients with peripheral vascular disease. This increase is the result of peripheral vasodilatation and increased cardiac output.

Much of the early work on peripheral vascular diseases has had to be discarded because of faulty technique, so there is a natural tendency to be cautious in accepting new observations. This investigation, however, seems to have been well controlled, and if it is confirmed it will undoubtedly stimulate others to explore its practical applications.

RISKS OF LOCAL SULPHONAMIDES

THE Home Office has drawn the attention of trade and other organisations to the Poisons (Amendment) Rules, 1947, which were made by the Secretary of State on Nov. 28. Among other matters these rules allow some relaxation in the restrictions now imposed on the sale of ointments and dressings containing sulphonamides. On and after Jan. 1, 1948, it will be lawful to sell these preparations without a doctor's prescription; but, as the ointments are subject to the provisions of section 18 (2) of the Pharmacy and Poisons Act, 1933, their sale must still be entered in the poisons book and the purchaser's signature obtained.

Most dermatologists will regret this step, for it is they who see the disasters which occur from the injudicious use of sulphonamides when employed for topical therapy. The necessity for obtaining the customer's signature may check sales, but there is a risk that injudicious self-medication will lead to major and minor catastrophes. In his masterly survey of the use of sulphonamides in dermatology Barber [1] expressed doubt whether the use of drugs of this series as local applications in superficial infective dermatoses such as impetigo contagiosa possessed any advantages over rational treatment with older and safer remedies. A similar view was forcibly expressed in the *Army Medical Department Bulletin*[2] in 1943 when sick-wastage from sulphonamide dermatitis was causing much concern. MacKenna [3] has pointed out that local applications of sulphonamides may cause three types of sensitisation—local sensitisation, general sensitisation, and photosensitivity. When local sensitisation occurs, an eczematous reaction with erythema and vesicle formation develops at the site of application; often this is interpreted by the patient as indicating that the original malady is gaining ground, and more vigorous measures may be taken to cure the infection, with disastrous results. General sensitisation is usually accompanied by exacerbation of the local lesions, fever, facial œdema, severe pruritus, and a generalised rash which may be erythematomacular or vesicular or occasionally bullous. Photosensitivity leads to the development of severe sunburn effects on areas of skin exposed to minimal degrees of sunlight, and this photosensitivity may persist for many weeks.

Dermatological literature throughout the world is studded with reports and discussions concerning the hazards of local sulphonamide treatment, but it is agreed that the drugs are used in a large number of cases without ill effect. Hitherto the disasters have been few, though their percentage incidence is not known. Phillips [4] found that among 2430 dermatological patients who passed through the wards of several military hospitals there were 100 cases of sulphonamide dermatitis—an incidence of 4·11%—but we have no knowledge of the size of the population at risk. Manufacturers will no doubt arrange for the preparations sold to the *public to* be clearly labelled so that the user is warned never to resembles that of any chronic wasting illness with secondary bronchopneumonia. In spite of a good appetite, the infant becomes increasingly undernourished. Cœliac disease rarely develops before the age of nine months, and the association of chest symptoms with loose stools should suggest pancreatic disease. The diagnosis can be confirmed by examining the pancreatic juice. All the pancreatic enzymes are deficient, but it is only necessary to estimate the trypsin, which is not difficult. A duodenal tube is passed, preferably under X-ray control, and the power of the juice to digest gelatin is analysed by the methods of ANDERSEN and EARLY.[6] Chemical examination of the stools and other laboratory tests are not of diagnostic value, for they merely reveal the presence of malabsorption and malnutrition. The glucose-tolerance curve is usually normal; nitrogen excretion is increased; and changes in the fat content of the stools are similar to those in cœliac disease, the fat being partially split by a lipase in the succus entericus but too late for proper absorption. The vitamin-A absorption curve is low, and this was at one time suggested as a diagnostic finding; but it may be found in any condition associated with impaired fat-absorption. The condition resembles cœliac disease in the wasting, distension, and diminished fat-absorption, but cœliac disease can be distinguished by the later onset of symptoms, the poor appetite, the lack of constant respiratory infection, and the normal enzyme content of the duodenal juice.

The fundamental cause of fibrocystic disease of the pancreas remains a mystery. At one time it was suggested that the whole condition might arise from vitamin-A deficiency, but more probably this deficiency, when present, is a secondary manifestation. Other possibilities are congenital malformations or inflammation of the pancreas during fœtal life. FARBER [7] believes that the basic lesion is a physically altered secretion which obstructs the small pancreatic ducts; and with this disorder he has found evidence of similar changes in secretion elsewhere in the body, especially in the lungs, duodenum, and biliary tracts. He postulates that this results from disturbance of autonomic nervous control, and he claims to have produced similar lesions experimentally in kittens. There is no doubt, from clinical observations, that lack of pancreatic juice is responsible for the diarrhœa and malnutrition, and these can be greatly improved by treatment. The intake of food must not only be sufficient to cover the inevitable losses through imperfect digestion, but enough to satisfy the requirements of appetite, energy, and growth. Full use should be made of modern predigested foods; casein hydrolysates can now be obtained in palatable form, and if given in sufficient quantity will supply all the protein needed. To these may be added extra carbohydrate, in the form of glucose, minerals, and vitamins; and pancreatin can usefully be given with solid foods when these are begun. Chemotherapy and penicillin have materially improved the outlook as regards the respiratory infection; but suppurative changes in the lungs, once started, are likely to progress, and the pancreatic lesion itself is irreversible. While the ætiology remains obscure, therefore, the outlook for these cases is poor.

Annotations

CHLOROMYCETIN: AN ANTIBIOTIC EFFECTIVE BY MOUTH

THE latest antibiotic is derived from a streptomyces found in a sample of soil brought from Caracas, Venezuela.[1] From filtrates of submerged aerated cultures of this organism a crystalline substance, chloromycetin, has been obtained. This is probably a chemical entity, since it has a definite composition, melting-point, and optical rotation, and it is unique in containing both nitrogen and non-ionic chlorine. Unlike penicillin it is stable over a wide range of pH and will withstand boiling for five hours. Chloromycetin is active in vitro in dilutions of 1 in 3,000,000, against *Brucella abortus*, *Bact. coli*, *Friedländer's bacillus*, *Proteus vulgaris*, and *Staphylococcus aureus*, and in much higher concentrations (1 in 80,000) against the tubercle bacillus. Judging by tests on mice it should be possible to get a concentration of 1 in 80,000 in human tissues without producing toxic effects. Its discoverers have not yet performed in-vivo tests with chloromycetin in tuberculosis, but screening tests with the pure material showed a striking chemotherapeutic activity against *Rickettsia prowazeki*, using chick embryos, and against a number of other rickettsial agents when tested on embryonated eggs.[2] From 24 eggs infected with the Gilliam strain of *R. orientalis* and protected by chloromycetin 8 live chicks were eventually hatched. The chemotherapeutic effect of the drug in mice infected with scrub-typhus was equally satisfactory, even when it was administered as late as ten days after infecting the animals.

These preliminary observations suggest that chloromycetin is well worth a clinical trial in tuberculosis and rickettsial infections. It not only is of low toxicity but has the great merit of being active when given by mouth, and in rickettsial infections it is effective late in the disease. At the moment the only promising drug against the rickettsias is *p*-aminobenzoic acid, which is not free from toxic effects.

IMMUNISATION AND THE DIPHTHERIA CARRIER-RATE

DOES mass-immunisation against diphtheria increase the carrier-rate among immunised children? In the opinion of Dr. V. F. Soothill,[3] M.O.H. of Norwich, this question has still to be satisfactorily answered. During the spring of 1944, a period of low incidence of diphtheria in Norwich, he made a random selection from the immunisation records of 100 children of each sex in the age-groups 2–5, 5–10, and 10–14 years. Care was taken to choose children attending well-scattered schools or welfare centres, or living in appropriate districts. As controls, a random selection of "comparable" children was made among the non-immunised. Immunised children were further divided into those whose post-Schick tests were known to be negative and those who had not been Schick tested. The checked counts of immunised Schick-immunes were 1333 immunised and 1061 non-immunised. Allowing for the immunised with and without negative post-Schick tests, these totals became: immunised 1377, non-immunised 1017. Swabbings from nose and throat obtained from all children in the latter two groups were examined for *C. diphtheriæ* and yielded 2 positive results in each group.

Unsatisfied with this statistically insignificant result, Soothill arranged for the experiment to be repeated, using the same groups of children, in the winter of 1944–45 when it was thought that *C. diphtheriæ* was more abundant. Except that a different school nurse

MASS RADIOGRAPHY IN THE EARLY DIAGNOSIS OF CHEST DISEASE

E. G. W. Hoffstaedt
M.D. Berlin
ASSISTANT PHYSICIAN, HOLYWOOD HALL SANATORIUM, WALSINGHAM, DURHAM

The early diagnosis of pulmonary tuberculosis and other important chest diseases still leaves much to be desired. Routine mass radiography of certain groups of the population was recommended by the Medical Research Council (1942) to detect unsuspected cases in the early asymptomatic stage. An ambitious programme was initiated during the war by the then Minister of Health, and the results of three surveys made by the Medical Research Council (1945) gave impetus to the scheme, which has since gained the enthusiastic support of many able and experienced workers in the field, particularly those who have witnessed the spectacular success of mass radiography in the Armed Forces.

Mass-radiography surveys of the civilian population, however, are a vastly different proposition from the screening or sifting of military personnel under Service conditions. Brailsford (1943) was one of the first to cast doubt on the wisdom and practicability of the official scheme; and Toussaint and Pritchard (1945) developed instead, with outstanding success, what has since been known as the Bermondsey scheme, in which practitioners are encouraged to send all their suspicious cases for X-ray examination.

It is perfectly true that "one type of case will be detected only by mass radiography: the person with unsuspected, possibly infective, chronic disease whose symptoms are insufficient to take him to a doctor" (Medical Research Council 1945). Active tuberculosis, however, has been found in only 0·4% of all the cases so far examined by mass radiography, and not nearly all of these have been symptom-free. Though Kahan and Close (1944) report that in none of their 138 cases of pulmonary tuberculosis picked up in a mass survey of naval ratings had the men ever reported sick or had symptoms such as to cause them to seek medical advice, in the surveys of the Medical Research Council (1945) of 79 "treatment cases" (out of 21,280 persons radiographed) only 29 were symptomless, and of the 50 patients with symptoms, 17 had already consulted a doctor. In other words, in rather more than a fifth of the "unsuspected" cases the patients had had symptoms for which they had sought medical advice, but in all of them the diagnosis had been missed because radiography was not used in time.

No information is given about the incidence of symptoms of non-tuberculous chest diseases found by mass radiography. The incidence of chest abnormalities other than tuberculosis discovered by mass radiography is 1–1·3%, but only a small proportion of these conditions, which include cervical ribs, pleural thickening, and calcified glands, need treatment. There will hardly be many asymptomatic cases of bronchial carcinoma, bronchiectasis, pneumoconiosis, or cardiovascular diseases which show definite radiological abnormalities.

The facts (1) that only by mass radiography can pulmonary tuberculosis and certain other chest abnormalities be detected in the presymptomatic stage (which is not necessarily an early stage); (2) that even the presence of certain symptoms, such as cough or lassitude, often does not lead the patient to the doctor; and (3) that in spite of definite radiological appearances physical signs are sometimes absent and tubercle bacilli not found in the sputum, have wrongly led to the conclusion that mass radiography is the method of choice in diagnosing early cases for treatment and thus in preventing the spread of pulmonary tuberculosis. It was hoped that nation-wide periodical mass radiography would soon become a reality, and the method was regarded as the answer to the question of diagnosis.

THE CLINICAL ASPECT

The clinician, be he tuberculosis officer or sanatorium physician, who has to deal with the cases as they arise sees the grave problem of early diagnosis of chest diseases from a somewhat different aspect. The impression gained in dispensary and sanatorium work has not borne out the claims made by the supporters of the official scheme. I have previously drawn attention to the fallacies inherent in the scheme and suggested more practical and economical ways of using mass-radiography units (Hoffstaedt 1944). I review here the histories of 40 out of 145 adult male inmates of Holywood Hall Sanatorium, co. Durham. In the table these 40 cases are divided into two groups—23 patients who had undergone mass radiography before admission to the sanatorium; and 20 cases where the diagnosis of pulmonary tuberculosis had been missed or had been established much too late because radiography had not been used early enough. Group II contains 3 cases which appear also in group I.

DIAGNOSTIC HISTORY OF 40 PATIENTS

I—23 *cases examined once or more by mass radiography*

A. Inactive clinically insignificant lesions	3	10
Pulmonary tuberculosis not yet developed at time of examination	7	
B. Active pulmonary tuberculosis already in advanced stage		7
Symptomless	2	
Ex-prisoner-of-war, mass-radiographed on repatriation	1	
Symptoms for 3 months	1	
Under medical treatment for 2 years with "bronchitis"	2	
Misdiagnosed on discharge from Army in spite of suggestive radiogram and rectal fistula	1	
C. Relatively "early" pick-ups		6
Total		23

II—*Original diagnosis in 20 cases of delayed action*

Pleurodynia	2	Neglect of family history	5
Pleurisy (no action taken)	4	Neglect of history or/and presence of:	
Influenza	4	Pleurisy	3
Bronchitis, cold, catarrh, &c.	6	Hæmoptysis	3
Fibrosis of lung due to asthma-bronchitis in presence of fistula ani	1	Radiography only on request	3
Anxiety neurosis (after 6 months' hospital "observation")	1		
Muscular rheumatism	1		
Bleeding from throat	1		
Total	20		

Group I (A) consists of 10 cases where mass radiography did not help in picking up unsuspected cases of early clinical pulmonary tuberculosis. In 3 of these men there was probably no active pulmonary tuberculosis when they were radiographed. Tubercle bacilli were never found in their sputum, and after three months' sanatorium observation, and six months or more after detection of the X-ray shadow, there was no spread or activation of the supposed lesion. These 3 "patients" represent the now well-known type of mass-radiography pick-ups who are a headache for the tuberculosis officer and would be at least as well off if never discovered and if left alone. The remaining 7 patients in group I (A) developed pulmonary tuberculosis from five months to more than two years after mass radiography had given a negative result. In their case mass radiography was futile, because the men were well at the time, the only indication for radiography being routine.

Group I (B) consists of 7 cases where active pulmonary tuberculosis was discovered by mass radiography to the apply the remedy for longer than seven to ten days, for sensitisation seldom develops if this rule is obeyed when local treatment with sulphonamides is first adopted. It will be interesting to see how they overcome the hazard of sensitisation from repeated applications of the remedies for short periods at irregular intervals. Meanwhile doctors in general practice should bear in mind the possible dangers.

THE PRACTITIONER'S INCOME

IN spite of (or maybe because of) the wealth of alternative calculations offered in the Minister's reply, many general practitioners have found a new and a puzzling pastime in figuring out what their individual incomes would be. The results, like those of other Christmas games, have depended a good deal on the psychological make-up of the participants. For a general practitioner in a mixed panel and private practice it may in fact be very difficult to determine just what his prospects are. It is of course easy to take the global sum of £40,826,250, which is to be paid for the general-practitioner service, and divide it by the likely number of practitioners (Mr. Bevan's estimate is 17,900), and so get an average income of £2280. But this is cold comfort. Few doctors will take much interest in this calculation: what they want to know is not the average income but their own expectations, and the truth must remain that there are so many variable factors that no simple formula can be of any real help. All we can do is to consider probabilities.

The first and most stable factor is the doctor's present panel list. Those patients already on this list will automatically remain with him if he joins the service—subject of course to their continued right to change their doctor whenever they choose. The patients on the panel list, if any, provide a firm and calculable nucleus, and one may confidently add to them their dependants. It is usually held that on the average the ratio of dependants to panel patients is 1·2 to 1. So for every 100 patients on his present list the doctor might reasonably count on some 220 in the future. After this, exactitude can hardly be pursued; for, except in closed communities served only by a single doctor or partnership, it is virtually impossible for any doctor to say with confidence at any given moment just how many private patients he cares for. Ledgers help very little. They seldom show the size of families, or keep a tally changing as some members of the family reach insurable age and others are born or die. In urban practice it is not always easy to know whether a particular family, not seen over a long period, is enjoying exceptionally good health or has transferred allegiance to another doctor. Again, few can be sure what proportion of the residents in their area will use the new service; which makes it difficult to guess the likely number of capitation fees, and even harder to estimate how much income may still accrue from private practice. Nor do we yet know how many doctors will be allowed to augment their incomes (and to what extent) by taking part in the maternity service.

On expenses some saving may be expected. The doctor will still (pending health centres) have to maintain his own surgery and his paid (and unpaid) staff, his car, his telephones, and his correspondence; but there should be a considerable saving for drugs, and dispensing, accountancy should cost less, and bad debts and the "free list" should disappear. The sources of occasional, or regular, additional income now enjoyed by general practitioners (such as insurance examinations, factory or other part-time appointments, pensions or recruiting boards) will not run dry, and some new springs are likely to appear; for the Minister speaks of "allowances for training assistants," and it seems certain, too, that in some areas graded specialist service in hospitals or clinics (paid on a sessional basis) will fall to the lot of those practitioners who are recognised by their colleagues as acceptable for this work. Add to this the hidden asset of superannuation rights, and the range of remuneration seems, as we said last week, reasonable though not lavish. It is true that the cost of living has risen steeply; but it will be recalled that Prof. Bradford Hill calculated for the Spens Committee that the gross income *from all sources* of general practitioners in 1939 was in the neighbourhood of £28,285,000. He assumed a similar total of practitioners to that now estimated by the Minister; so we can justifiably contrast his global figure with that now offered by the Treasury. The £40,826,250 offered does therefore represent a substantial increase, particularly when one remembers that in addition to it the gross total future income of doctors will include private fees for general practice; the remuneration received from industry, insurance societies, the hospital boards, and the Ministries of War, Pensions, Education, &c.; the fees received for public and private maternity work; the allowances for training assistants; and the State's share of the superannuation contribution.

Just how it will all work out remains to be seen. Inequalities of opportunity in the early days seem inevitable, though they need not amount to injustice if the time remaining before the appointed day is wisely used. In any service paid preponderantly by capitation fee it seems obvious that opportunity should be provided, well before the commencement of operation of the service, both for the doctors to express their willingness to serve, and for patients hitherto uninsured to state their intention of using the service and their choice of doctor. Any curtailing of this preliminary preparatory period, which should last at least three months, would mean that an inordinately large share of the pool would go to those doctors fortunate enough to have already a very large panel; or skilful enough to be able to collect quickly the maximum of signatures of their newly arriving State patients. Once we recognise this, and are agreed on the undesirability of any unfair and undignified last-minute scramble, it becomes obvious that the time for decision is short—probably no more than half of the six months that separate us from July 5. It is later than we think. It is all the more urgent, therefore, for practitioners to relate the Minister's proposals to their own practices and lives, and to decide whether his offer is one which they can accept.

B.M.A. AND PLEBISCITE

ON Dec. 17 the council of the British Medical Association met to consider the Minister's reply to the Negotiating Committee. In a statement to the press it says:

> ". . . for nearly a year we have worked at the conference table to no purpose. There remains one final question and one central issue. Does the service as described by the Minister conflict with the traditions and standards of a great profession? There is only one answer the council of the association can give to this question. It does so conflict."

On Jan. 31 a plebiscite of the whole profession will be taken.

THE gift of over £1 million which South Africa made last year to the British people included £106,025 from Durban and Natal. *Of this sum* £106,888 is to go to the Institute of Child Health of the University of London, for a new separate building near Great Ormond Street Hospital. This will house a model welfare clinic and other services developed with the local authority. The institute's director is Prof. Alan Moncrieff.

(4) The insignificance of negative sputum results, particularly of one single direct smear, both for the diagnosis of pulmonary tuberculosis and for differential diagnosis, does not seem to be common knowledge. In fact "routine sputum examination," as suggested by Brailsford (1944), would do more harm than good if any reliance were to be placed on negative returns.

(5) Let us be frank about another psychological phenomenon. There is undoubtedly also a certain, mostly unconscious, reluctance among doctors to accept and to pronounce so serious a verdict as pulmonary tuberculosis or carcinoma. And from this very reason, though few will be prepared to admit it, any negative findings on either physical or bacteriological examination will be accepted with a sigh of relief; and, hoping for the best, the doctor dismisses his original suspicion much to the detriment of the patient.

(6) Another unpalatable fact has to be faced: doctors are not always so tuberculosis-minded as they should be. This is due to the inadequate training of medical students in tuberculosis, a deficiency of the curriculum which has already been acknowledged by various authorities.

(7) Harassed and overburdened general practitioners have not always an opportunity to take detailed case-histories of patients with minor symptoms—and it is usually with minor complaints that the trouble starts—who want a bottle of medicine rather than being questioned, stripped and tapped, and sent from one place to another, and all the rest of it.

(8) The most important factor leading to missed diagnosis and to serious delay in diagnosis and treatment is the omission of chest radiography as part and parcel of a routine chest examination—the failure to grasp that "examination of the chest is incomplete unless it includes a roentgenographic study" (Goorwitch 1944). One of the main factors contributing to this fateful omission is the lack of sufficient facilities for radiography available to the general practitioner and within easy reach of the patients, particularly in small towns and rural districts. Moreover in many areas tuberculosis dispensaries are not equipped with an X-ray plant, which means many journeys and fares and great loss of time for the patient. It must also be remembered that there are patients who dislike attending a tuberculosis clinic.

IMPRACTICABILITY OF NATION-WIDE ROUTINE MASS RADIOGRAPHY

The supporters of the official mass-radiography scheme believe, and want to make us believe, that faithful application of the official medicine is the real thing. I wonder whether these enthusiasts still believe, as they did five years ago, that "the X-ray manufacturers will shortly be ready to provide apparatus as soon as they receive orders" (*Tubercle* 1942). How are they going to turn out the teams of skilled personnel, technical and medical, to man the units which apparently were to come off the endless belt like cannon shells in munition factories? The bitter truth is that up to the end of June, 1946, only 19 units altogether were operating in England and Wales (*Lancet* 1946), which to that date had examined 1,111,000 people with the rather meagre result of picking up 4200 cases (0·4%) of active pulmonary tuberculosis. Even supposing it were possible to provide another 19 or 20 units together with skilled personnel within the next three years or so, we should still not have made much headway on the road to Utopia.

Toussaint and Pritchard (1943) said that "to deal with even 50% of the London population 20 units will be required," and Brailsford (1943) estimated that "for the Birmingham area of 2,000,000 inhabitants we should need 80 units for 3-monthly examinations." Even if Brailsford's figures are cut by half, it is obvious that, with the machines and the personnel now at our disposal, it will be impossible for many years to come to survey the working population of this country even once, let alone periodically every six months.

Apart from the futility of the scheme, the expenses in material and working hours, the amount of energy and skill employed, are utterly out of proportion to the poor return—an average of 0·4% of active pulmonary tuberculosis and a very small percentage of other chest diseases, a good deal of which could and should be discovered by ordinary routine examination under an adequate and up-to-date diagnostic service.

A wave of positive criticism against the official scheme is rising. Heaf (1946) and Jessel (1945) state frankly the impracticability of surveys of a whole population. Jessel (1945) and Hoyle (1945) emphasise the potential danger of one normal radiological report in creating a sense of security which may delay diagnosis later. I have already drawn attention to this point (Hoffstaedt 1944). Hoyle concludes: "We have yet to learn how best it may be used and what the unavoidable limitations are of a method capable at once of revealing pulmonary tuberculosis at its most amenable phase and yet of failing to do so in practice, except for a fortunate few who happen to be in this phase at the precise moment of the examination."

Brailsford (1945) lucidly demonstrates the limitations of mass radiography and suggests the use of this method for limited, selected, and essential services. He, like England (1946), sees the danger of straining the dispensary system by overflooding it with insignificant cases to the detriment of those in need of attention and treatment. England's main criticism deals with the 25–50% leakage of the "drag-net" resulting from the voluntary character of the scheme, because it is the very fraction of the population most likely to show a high incidence of disease which will most probably escape the wide mesh of the net.

The wastefulness of routine mass radiography, if it ever attains its object of periodical surveys of stable population groups, is shown by Reid's (1943) revelation that the incidence of new cases of active pulmonary tuberculosis among the employees of the Metropolitan Life Insurance Co. dropped in ten years from 0·4% to 0·07%. This observation is supported by the report of the Medical Research Council (1945) that the incidence of newly discovered cases of active pulmonary tuberculosis dropped from 0·3% to 0·1% in a year when the same group was re-examined.

THE REMEDY

The diagnosis of disease is in the first instance the business of the family doctor. The general practitioner is not only just a clearing-station, but far more—the first line of defence. Before the practitioner can play his most important part in any health service which deserves the attribute "comprehensive and efficient," several basic conditions must be fulfilled.

The first essential condition is that "for diagnosis, doctor and patient must meet" (Trail 1942). As this cannot be taken for granted, something has to be done about it. It has been shown over and over again that too much time is lost before the patient sees the doctor (Mann 1943, 1946). Health education on a nation-wide scale, starting at school, must create and foster a sense of health responsibility, and at the same time the masses must be educated to look after themselves and to seek proper medical advice (not a bottle of medicine or pink tablets) in time. The modern tendency to spoon-feed the people weakens and eventually destroys the sense of self-responsibility and of independence which is the very essence of civic liberty. A wrong notion of what is meant by "guaranteed security" makes the people too much dependent on some sort of State assistance or public services which will take all the trouble and will benefit of the patient; but in all of them the disease was already advanced, and mass radiography therefore did not provide early diagnosis. Of these 7 patients 2 had no symptoms, though one of the two had already developed bilateral disease with a cavity and positive sputum. Of the remaining 5 in this group 1, an ex-prisoner-of-war, had far-advanced tuberculosis when he underwent mass radiography on repatriation; 1 had had symptoms for three months when examined; and the remaining 3 were cases of "missed diagnosis" which should really have been found out without being left to chance discovery by mass radiography. These 3 cases are discussed below.

Group I (C) consists of 6 cases where a relatively early diagnosis of pulmonary tuberculosis was established by mass radiography.

Group II consists of 20 cases where the diagnosis of pulmonary tuberculosis had been missed, leading to delay in treatment; they include 3 cases from Group I (B). Among the original diagnoses "pleurodynia" figures twice; this is no diagnosis but merely a symptom.

In 4 cases the patients were treated for "influenza"; it would be grossly unfair to blame any doctor for such a diagnostic error, particularly during seasonal outbreaks of genuine influenza; but the subsequent history and, if present, a family history of pulmonary tuberculosis should arouse suspicion and lead to investigation of sputum and by radiography.

Bronchitis, catarrh, cough, and cold were the original diagnoses in 6 cases. One of the worst had been treated for "smoker's catarrh" by an Army doctor. Two of these patients, who were eventually discovered by mass radiography, had attended their doctor on and off for two years.

In 4 cases even the original diagnosis of pleurisy did not lead to further action until after most valuable time, from six months to two years, had been lost. To diagnose a pleurisy and to leave it at that without further radiography is a very serious omission.

One patient had been discharged from the Army in 1943, after six months' "observation" without ever having been radiographed, with the diagnosis of anxiety neurosis and nervous disability. When he was eventually radiographed three years later, widespread bilateral pulmonary tuberculosis with a big cavity had developed.

Another ex-Army patient had had an ischiorectal fistula since 1941 and had been discharged from the Army in 1942 with the diagnosis of lung fibrosis due to asthma-bronchitis, based on the radiogram without any regard to the presence of the fistula. In February, 1946, hæmoptysis, huskiness, and listlessness had developed. No tubercle bacilli being found in the sputum, no further action had been taken. (This shows clearly the fallacy and actual danger of negative sputum results.) In April, 1946, he had been mass-radiographed; but no report had been received. Only after inquiry in June, 1946, had he been referred to a dispensary, where tubercle bacilli had been found in his sputum, and tuberculous lesions in the upper and middle zones of the left lung.

One patient, in spite of a history of pleurisy in 1944, had been treated for six months in 1945 for muscular rheumatism until a hæmoptysis led to the diagnosis of pulmonary tuberculosis. It is strange that his family doctor had apparently not taken into consideration the highly suspicious and significant fact that both the mother and the sister of the patient had died of pulmonary tuberculosis.

Failure to take the family history into account was significant in 4 other cases. One case had been diagnosed as "bleeding from the throat." The history or the presence of hæmoptysis had been neglected in 3 cases. The omission of chest radiography in a case of hæmoptysis, however small, must be considered grave neglect. Though there are several non-tuberculous conditions which may cause a hæmoptysis, the spitting or coughing up of blood, however little, usually spells serious disease.

Finally one rather exceptional case of "missed diagnosis" is worth mentioning. A miner, aged 22, whose two sisters had died of pulmonary tuberculosis, had had pleurisy in August, 1945, and pleurisy and hæmoptysis in December, 1945, and June, 1946. After that the patient had insisted on being radiographed, with the result that he was admitted to sanatorium in September, 1946, with extensive tuberculous lesions all over the right lung and the left middle zone.

In 3 cases of this group radiography, which had at once clinched the diagnosis, had only been done on either the patient's or his mother's request.

In these 20 cases there was a time-lag, from three months to three years, between first reporting to the doctor and the establishing of the diagnosis by radiography. In most cases the delay exceeded six months.

DISCUSSION OF RESULTS

If in 20 out of 145 sanatorium patients—i.e., in 14% of the sanatorium population—pulmonary tuberculosis was not diagnosed in time, in spite of suggestive symptoms and/or suggestive history, we have no reason for complacency. If, on the other hand, the expensive machinery of mass radiography used in 23 cases was a complete waste in 10 of them, and if only 6 of the 13 pick-ups were early cases whereas 3 cases had been previously missed in spite of suspicious symptoms because they had not been radiographed in time, then there seems to be room for improvement in the use and organisation of radiography as an aid to early diagnosis of chest disease.

It is perhaps fair to assume that the experience in this sanatorium, as illustrated by the analysis of the present 40 cases, is similar to that of other clinicians; and what is true of pulmonary tuberculosis will most probably be true of other chest diseases. Mann (1943) found an average delay of $3^{2}/_{3}$ months from onset of suggestive symptoms till the patient consulted the doctor, and a nearly equal delay from the first attendance until reference to the dispensary. For obvious psychological reasons general practitioners are sometimes reluctant on mere suspicion to send a patient to a tuberculosis dispensary. Some patients refuse to attend a tuberculosis clinic for fear of publicity.

As regards early diagnosis, Fraenkel (1947) found, in five years' sanatorium admissions, only 2 cases of the earliest recognisable form of post-primary pulmonary tuberculosis. The failure in practice to diagnose tuberculosis at a reasonably early stage cannot be more impressively demonstrated than by the most alarming and disquieting statement that about half of all deaths from pulmonary tuberculosis take place within a year of notification. What, then, are the reasons for this sorry state of affairs, and what is the remedy?

CAUSES OF DELAY IN DIAGNOSIS

(1) As Jessel (1941) and Trail (1942) point out, there are reasons inherent in lung disease. The onset of the disease—e.g., pulmonary tuberculosis, pneumoconiosis, bronchial carcinoma—is usually so insidious that the patient does not seek medical advice in the early stage. It is this initial paucity, or even absence, of symptoms that forms one of the strong points in favour of routine mass radiography.

(2) Varied and deeply rooted psychological reasons on the part of the patient which have not yet been appreciated sufficiently and must be properly understood: ignorance, indolence, carelessness, and ill-developed sense of health responsibility, on the one hand, and inability to face and to accept a serious disabling disease, fear of insecurity due to loss of work, and other sources of anxiety, on the other hand, prevent many a patient from appreciating such symptoms as may be, and very often are, present.

(3) The well-established fact that chest disease of considerable extent may often present to the examining physician only inconclusive physical signs or no signs at all do not yet command due attention.

LOCAL EXECUTIVE COUNCILS

WE publish this week a further list of the chairmen and medical members of these councils. A council has still to be set up for the Scilly Isles. Earlier lists appeared in our issues of Sept. 6 (p. 364) and Sept. 27 (p. 485).

Anglesey
Colonel R. D. Briercliffe (chairman); Drs. T. A. Griffiths, Leslie Jones, R. O. Jones, J. Lloyd Lewis, W. Parry-Jones, N. B. Thomas, G. P. Williams.

Barnsley
Alderman E. Sheerien (chairman); Drs. L. V. Broadhead, S. Curry, J. P. J. McMahon, Norris Pick, J. Helen Ritchie, A. Birtles Slack, E. J. Williams.

Bradford
Alderman Kathleen Chambers (chairman); Drs. D. Black, R. Chester, R. Craig-Hanson, J. Douglas, G. Priestman, M. B. Gathorne Sinnette, R. H. Sunderland, W. N. West-Watson, J. Wright.

Breconshire
Mr. Tudor Watkins, M.P. (chairman); Drs. S. N. Chopra, T. L. Davies, D. L. Lees, R. G. B. Lusk, S. H. Pugh, T. R. Sutherland, W. W. Wilson.

Buckinghamshire
Mrs. O. H. Paterson (chairman); Drs. F. C. Haward, J. M. L. Love, R. W. McConnel, R. V. F. Mercer, G. W. H. Townsend, H. Vickers, D. J. B. Wilson, W. Young.

Coventry
Councillor J. Latham (chairman); Drs. K. E. Barlow, W. D. Coghill, H. N. Gregg, R. Laverty, H. P. McNamara, N. J. L. Rollason, C. F. Turner.

Cumberland
Captain J. M. Gatheral (chairman); Drs. E. Braithwaite, W. Fraser, V. C. J. Harris, R. A. Quinn, A. K. Rankin, J. Sachs, G. H. Thomson.

Doncaster
Lieut.-Colonel W. F. Bracewell (chairman); Drs. J. Ashforth, Bessie E. Cook, J. M. Hain, A. E. Huckett, B. Lyons, J. L. McEwen, H. F. Renton.

Gloucester County and City
Mr. A. B. Cooke (chairman); Drs. C. C. Carson, H. K. Cowan, T. A. Fyfe, J. H. Grove-White, M. M. St. G. Johnstone, J. R. Miles, W. G. Murray-Browne, T. E. N. Simpson.

Grimsby
Mr. A. G. Pearson (chairman); Drs. J. Cottrell, W. N. Hood, J. D. Horsburgh, J. A. Kerr, F. Martyn, P. R. Riggall, E. A. Robertson, H. J. Thomson.

Halifax
Mr. W. G. Hill (chairman); Drs. L. G. Allan, W. H. Craven, W. O. S. Hornby, D. L. S. Johnston, D. G. S. Mackay, James Morrison, James Tidd.

Hastings
Alderman F. W. Chambers (chairman); Drs. E. D. Blunt, R. Carpenter, F. J. Cutler, E. J. Glynn, A. F. Hall, W. Magowan, G. N. Wood.

Lincoln County Borough
Miss B. M. Sharpley (chairman); Drs. T. W. Chapman, P. S. Cheshire, T. O'Brien, W. V. Semple, G. D. Summers, M. M. Tannahill, Constance Vallange.

Lincolnshire (Kesteven)
Mr. W. K. Carter (chairman); Drs. D. S. Buchanan, K. M. Foster, C. Frier, J. A. Galletly, F. J. Jauch, E. C. Till, E. D. M. Wright.

Lincolnshire (Lindsey)
Mr. H. A. Howden (chairman); Drs. J. R. Baker, F. P. H. Birtwhistle, H. B. W. Smith, J. H. Ward, T. J. T. Wilmot, T. R. Wilson, S. Wray.

Manchester
Mr. F. B. Dinsdale (chairman); Drs. C. Metcalfe Brown, A. F. Dunn Carrie, W. Chadwick, D. R. Goodfellow, Alick McGlashan, R. G. McGowan, J. I. Milne, F. Reynolds, P. J. Webb.

Middlesbrough
Mr. B. E. Ainley (chairman); Drs. P. M. Barclay, J. C. Clark, J. W. L. Dickson, F. W. Hebblethwaite, J. E. Howell, B. F. Longbotham, R. W. Murphy.

Nottingham County and City
Mr. R. P. Marchant (chairman); Drs. R. P. Anderson, R. O. Brooks, R. Davidson, J. H. Francis, H. N. C. Jaffé, J. L. T. Knox, T. S. McKean.

Portsmouth
Councillor Mrs. M. H. Childs (chairman); Drs. R. H. Emmett, L. M. Maybury, K. V. Mead, W. Meikle, Una Mulvany, Claude Robertson, H. E. Suter, A. B. Williamson.

Radnorshire
Captain Harri Williams (chairman); Drs. G. H. H. Booth, F. J. H. Crawford, J. G. Garman, J. E. Jenkins, R. H. Jobson, J. D. O'M. Poole, R. J. Walker, W. W. Wilson.

Rotherham
Alderman A. Buxton (chairman); Drs. D. W. Barr, E. A. Coldrey, D. P. K. Jockal, C. W. A. Lister, J. J. Morgan, G. H. Sedgwick, A. Taylor.

St. Helens
Mr. D. V. Phelps (chairman); Drs. D. Campbell, J. L. Chisnall, F. Hauxwell, R. M. Jones, H. A. Lomax, A. A. W. Merrick, J. G. O'Keeffe, T. Sutton.

Southampton
Mr. F. Woolley (chairman); Drs. G. H. Barendt, B. Bourke, A. McD. Grimston, A. Morrice, J. B. A. Reynolds, E. Sakoschansky, J. E. A. Simpson, H. C. M. Williams.

Surrey
Alderman Mrs. Amy Woodgate (chairman); Drs. D. Dunlop, R. V. Goodliffe, T. W. Morgan, E. L. K. Sargent, N. E. Waterfield, K. Watson, D. F. Whitaker.

Wakefield
Alderman A. Carr (chairman); Drs. C. S. Broadbent, A. M. R. Heron, H. T. Knowles, P. J. Rafferty, J. J. Reynolds, S. P. Sloan, T. Walker.

Medicine and the Law

In the Wrong Carton

LAST week the Hammersmith coroner considered the case of a man of 42 who died suddenly after an injection for varicose veins.[1] The doctor who had been treating him said that the patient had previously had two injections. When he returned for a third injection the doctor drew off 2 ml. of 'Etalate' from an almost empty bottle. In order to make up the amount to 5 ml. he then took down from his cabinet a second bottle in a container labelled 'Etalate,' and withdrew from it a further 3 ml. In so doing, he saw only the rubber cap of the bottle, which remained in the container. The 5 ml. of fluid thus obtained was injected into the thigh of the patient, who collapsed and died two minutes later. Afterwards the doctor found that the second bottle contained adrenaline solution, not etalate. A fortnight earlier he had mislaid a bottle of adrenaline which he usually carried in his bag, and despite search it had not been found. Workmen were decorating his ground-floor room, and on the night before he saw the patient he had moved most of his equipment into a room on the first floor, where the injection was given. He concluded that the lost bottle of adrenaline must have found its way into the etalate carton.

A verdict of death by misadventure was returned.

[1] *Evening Standard*, Dec. 15.

readily come in whenever required—though then often too late.

It therefore seems that, except for certain hazardous industries where routine mass-radiography surveys are essential, it is a psychologically wrong approach, and not without danger, to bring the X-ray machine to the factory and to the office. The better plan would be to see that the really deserving people, the suspected cases, are sent to the X-ray department through the agency of their own doctor.

The widespread indolence and complacency of so many irresponsible and ignorant people must gradually but systematically be overcome. The raising of the school-leaving age is perhaps a unique opportunity for health education. The cinema should produce an equivalent to the B.B.C. talks of the Radio Doctor. There is plenty of scope for effective health propaganda. To maintain the proper doctor-patient relationship, which is the foundation of any satisfactory health service, people must be encouraged to see first of all their own doctor.

It is certainly commendable that mass-radiography units direct their activities towards people in whom the presence of a chest disease may be suspected; but it is definitely wrong for them to organise so-called open sessions and invite the public, by advertisements in local papers and transport, to attend these sessions. This is contrary to professional usage and does not fit in with the generally accepted practice of outpatient clinics and public-health clinics.

It is the general practitioner that must be encouraged, nay urged, to send patients for radiography. In the National Health Service the health centres, as they gradually come into being, will provide facilities for radiography. It is here that mobile mass-radiography units could be employed with the greatest benefit to the public (Hoffstaedt 1947). Adequately equipped health centres for group practice, taking the place of the often poorly equipped one-man shop called the surgery, will eventually give the practitioner the chance of examining patients properly. Here also basic laboratory facilities must be provided. Last but not least, the help of a trained nurse or of a receptionist will enable the practitioner to take proper case-histories, preferably on standard case-sheets with relevant anamnestic and symptomatic items, including family and occupational history. After all, history-taking is one of the most important and revealing parts of an adequate examination.

A much better training of the medical student in tuberculosis and chest diseases and in the appraisal of X-ray photographs is an urgent necessity. It must be understood by doctors that arguments about stethoscope versus X rays are pointless, because physical chest examination and radiography are not alternative but complementary methods, each of them indispensable and essential, supplementing, never substituting, each other. Maxwell (1946) rightly postulates: "A practitioner who did not insist on an X-ray examination of a suspicious chest case, especially after hæmoptysis, might be sued for negligence." And Toussaint and Pritchard (1944) logically visualise the same legal consequences for omission of a chest radiogram as those already existing under the present law for neglect to radiograph a bone injury in time. Even "the man in the street is coming to know that a chest examination without a film is of comparatively little value" (Tattersall 1946).

THE PLACE OF ROUTINE MASS RADIOGRAPHY

In existing circumstances the pursuance of the official scheme of indiscriminate routine mass radiography is utopian. The Medical Research Council (1942) rightly said that "owing to the limitation of apparatus likely to be available in this country concentration at the present time should be upon those groups where through the nature of employment (e.g., silicosis producing industries) or the composition of the population at risk a relatively high incidence of unsuspected pulmonary tuberculosis is likely to be found." Dick (1946), also recognising the continuing scarcity of machinery, allocates at least one afternoon each week to the examination of contacts and referred cases. Heaf (1946) and Brailsford (1944) recommend the use of the available units for those sections of the population where there is the highest risk: hazardous industries, contacts, and suspicious cases with symptoms. In hazardous industries mass radiography should also be used for pre-employment examination (Gooding 1946, Heaf 1946).

Routine periodical mass radiography of contacts would greatly contribute to the early diagnosis of pulmonary tuberculosis and at the same time help greatly the routine work of the chest clinics or dispensaries (Hoffstaedt 1944, England 1946). That the examination of contacts by mass radiography deserves first priority is clearly shown by the results published by Dick and Thompson (1946), who found the incidence of active pulmonary tuberculosis among contacts five times as high as in the general population; by Hahn (1943), who found similar figures among consorts of persons with pulmonary tuberculosis; and by Couts (1947), who found an incidence of 5·5% and 6·3% respectively among contacts examined in 1944 and 1945.

In short, it is the suspected rather than the unsuspected section of the population on which we have to concentrate our efforts to make radiography the most powerful weapon in our fight against the white plague.

SUMMARY

Of 23 adult male sanatorium patients who had been examined in the course of routine mass radiography, this procedure had been valueless in 10. Of the other 13. only 6 were diagnosed in an early stage.

Another group of 20 cases illustrates the need for much better training of medical students in tuberculosis and chest radiography.

The impracticability and undesirability of nation-wide routine periodical mass radiography are shown.

It is suggested that mobile mass-radiography units should be employed at health centres and should concentrate their attention on workers in hazardous industries, on contacts of known patients, and on suspicious cases with symptoms—i.e., the suspected rather than the unsuspected section of the population.

My thanks are due to Dr. J. W. Gray, medical superintendent, Holywood Hall Sanatorium, for permission to publish and for his kind and helpful advice.

In England Now

A Running Commentary by Peripatetic Correspondents

As soon as Siva appears on the scene, at the Indian Exhibition,[1] stone and bronze begin to dance; they can hardly do less, for he is the Lord of the Dance, the emblem of cosmic rhythm. Symbolic additional arms, weaving into the light-hearted pattern, astound the unaccustomed eye only for a moment; and gods and godlings crowd together, supple as van Gogh's fir tree, until every group seems rustling with movement, or rushing up in flame. How strangely quiet, after this, are the rooms of little brilliant pictures, where flowers enamel the ground and a blue Krishna sports with the milkmaids. They are as bright and vivid as pictures in a missal—

> . . . "Where all is smaller than a wren,
> But has high towers, meteors, and men,
> And suns and spouting whales."

Whales, indeed, are not to be seen, but there are fawns and hounds and horses, and a Persian richness of flowers and trees and shining silks.

* * *

An exhumation I attended a few weeks ago was almost a jolly occasion. Our proceedings started with an excellent cup of coffee and a welcoming smile from a Sister of Charity dressed in flowing black except for her white wimple and a large dangling wooden rosary at her waist. Two of my colleagues were also present—the local medical officer of health, bearing a Home Office exhumation order, and a physician from a neighbouring town, who, like myself, had consented to act as an official medical witness. The morning sun shone into the anteroom while we speculated quietly about our part in the coming ceremony, which had just begun with the chanting of the *Veni Creator* in the adjacent chapel.

Fifty years ago the foundress of the Order, after a saintly life, had died and been interred in a lead coffin in a deep vault beneath the wooden floor of the little church. Convinced of her outstanding sanctity, the community had applied to the Holy See for official inquiries to be made, hoping that these would lead to her beatification. I don't know much about the details except that these inquiries are thorough beyond belief.

First you dig up the body. This had just been done by a small group of blue-overalled workmen, who had torn up the floor, opened the vault, and raised a grimy leaden shell up to floor level and left it by the side of the hole. Seated on a chair in the middle of the little nave was the Reverend Abbot of an adjacent monastery with three or four monks in Benedictine habits, one of whom was the postulator, pressing the cause and acting as master of ceremonies for the occasion. Along one side of the chapel sat a line of nuns of the Order, all Reverend Mothers of branches of the community, some of whom had come half-way across the world to be present. We were given seats opposite the sisters, about three feet from the coffin, around which stood the six workmen. A long trestle table with a heap of rosaries and sacred emblems at one end took up much of the space, and in the background the good nuns had thoughtfully provided several hand basins, hot water, and a large bottle of 'Dettol.'

The Abbot rose and held up a document from the ecclesiastical authorities, the large stone of his finger ring making a touch of colour against the sombre black of his companions. The paper was read, authorising the exhumation and examination of the body, provided that no other bodies were disturbed and that all the process should conform with the laws of the civil authority. Here he turned to the M.O.H. and asked if all was in order to proceed. Receiving an affirmative answer Holy Church got down to serious business. One by one, with their right hands touching a large copy of the Gospels placed in the foreground, the small group of priests bound themselves by a formidable and comprehensive oath to give nothing but true and honest testimony of all that should be seen or found. Then two sisters from the end of the line came forward to be sworn and questioned by the Abbot. They agreed that they had witnessed the interment and that to the best of their knowledge the body had lain there undisturbed for fifty years. Then the chaplain pronounced the solemn curse of excommunication on any person who should, from whatever pious motive, disturb, add to, or remove anything from the coffin about to be opened. Lastly every one of the workmen and we ourselves were sworn in like manner. By this time I felt rather like the Jackdaw of Rheims; and we all know what happened to him.

The foreman of the attendants began work on the shell, introducing the point of a clasp knife into the edge of the lead lid and gently tapping the blade along the whole length of the side to work his way round to the starting-point. He was followed by two of his mates with screwdrivers who gently levered up the small nails securing the lead edges to the wood. The air of expectancy throughout the assembly could almost be felt.

The Roman Catholic Church is not easily persuaded to make new Saints, and first demands overwhelming evidence of their sanctity. I believe that among other things at least two major miracles connected with the Saint must be cited, and the evidence must be faultless and convincing. Later a very sceptical gentleman is briefed as Devil's Advocate and instructed to tear the evidence to shreds. Complete absence of corruption many years after death (embalming and the like being excluded) is a good start, and no doubt many hopeful hearts awaited something of the kind here. It has apparently occurred a good many times in the past. Still we, as doctors and medical sceptics (not to mention our oaths), had no intention of being deceived in any matters to come.

At last the outer lid was prized up and the inner wooden shell revealed with a damp white mould streaking its outer surface. The workmen gently lifted the heavy lid and laid it aside while the foreman easily levered up the light covering of the inner shell lying in a set of grooves. As witnesses we then rose to examine the contents.

Clothed in her black habit and scapular, a small body lay supine, the hands clasping a rosary and a withered spray of flowers, with a faded piece of paper, almost completely decomposed but bearing the faint handwriting of her solemn vows made a hundred years before, between her fingers. From some fault in sealing at the time of burial the coffin was not entirely airtight, and we found the body and outer clothes sodden with moisture. The lining of the shell, the outer clothing, and even the black felt slippers were intact, but the stockings and body covering had almost entirely rotted away. As a whole the body and limbs had retained their normal shape, but the tissues covered by clothes had become converted into adipocere of a white and almost granular consistency. The uncovered face and hands were shrunken and mummified to a brown colour, with the features unrecognisable but the finger-nails intact, though they became detached at a gentle touch.

The quiet voice of the postulator adjured us to make as thorough an examination as possible and to give an exact account of the condition of the body and all the limbs. I called to two of the sisters to free the heavy leather girdle and expose the rest of the body so that I could examine it while my physician colleague took notes. Then we adjourned to the trestle table to wash our hands. A nun found us a typewriter and carbon papers, and my colleague and I composed a joint report under the scrutiny of the M.O.H.

Meanwhile, the long file of nuns passed round the shell to take a last look at their foundress and to touch the exposed body with rosaries and crucifixes. The Abbot and his attendant clergy sat and watched the opened coffin till, after a formal question as to whether we wished to make any further examination, the order was given to reseal the leaden lid. We read, checked, and signed four copies of our detailed report and handed them to the postulator, who thanked us heartily for our help and then casually asked us if we had noticed anything unusual about the body, having regard to all the circumstances. We could only find him one sentence in our report which said: "There was a remarkable absence of odour when the coffin lid was raised." And that, with the body a mass of adipocere, dripping wet clothes, and obvious access to moulds, we both thought at least slightly unusual.

[1] The "Exhibition of Art, chiefly from the Dominions of India and Pakistan" at the Royal Academy of Arts is open until Feb. 29, 1948; weekdays 10 A.M. to 7 P.M., Sundays 2–7 P.M.

* * *

It was somewhat of a shock, though a pleasant one, to change from our austere British food to the full, nay surplus, diet of America. At first I ate freely and put on 7 lb., but I soon found that I had to limit my intake if I wished to feel at my best. One's constitution undoubtedly accommodates itself to austerity.

Two points about the meals struck me as noteworthy —the constant presence of iced water and the usual absence of wine at table. The glass of iced water is served to each guest at every meal—breakfast, lunch, tea, dinner—before anything else is brought. After a time one gets to like it, though it does seem out of place when brought with a pot of hot tea. Once when I asked my hostess why it was always served she answered, "Well, we should not consider the table properly laid unless each person had it." Whether it is a good or bad thing for the stomach is not for me to say; an experienced physician thought it was harmful, but this may have been a case of sour grapes. It is the custom to drink cocktails—definitely in the plural—before the meal; but as a rule water, iced of course, was the only drink during the meal. Since I happen to be a teetotaller this was quite convenient.

* * *

Once upon a time, as you will remember, there was a princess who had stepmother trouble. Her eleven brothers were turned into swans and she got carried off and married to a king. She used to leave his bed (it says that in the book) to collect nettles from the churchyard and to weave them into coats of mail, specific cures for those who are swans by day. She was about to be burned as a witch when it all came right, all but the eleventh brother's arm which remained a wing. You remember? Hans Andersen assures us that the diagnosis of being a witch rested on her refusal to speak and her going to the churchyard; but I doubt if he got the case-history right. How was he to know about Feldberg, Anrep, and their colleagues?[1] It is only too obvious now. The woman was pregnant, the nettles planned to do their stuff with acetylcholine, histamine, and something, but she had a high histaminolytic index and so although she felt the pain she didn't get nettle-rash. That's why they thought she was a witch; probably Andersen thought the churchyard story had better sales-value.

It has taken me forty years to make the diagnosis of pregnancy in this case. Is that in time for those who live happily ever after?

* * *

She was one of the cases in which the formidable battery of psycho- and physico-therapies of modern psychiatry had failed. Over the weekend at home she smashed all her crockery and put most of her clothes into the fire. Then somebody remembered that a gynæcologist had suspected gland trouble because of the faun-like hirsutes she had from the belt downwards. The big gun of endocrinology was to come up all the way from London and matron was told to get the patient prepared for examination. After the experts had put their heads together and the gynæcologist had pleaded his case for virilism, we stood around the bed to see the evidence. I wish I could describe his face (and ours) when it was found completely removed, shaved off by our well-trained and zealous matron.

* * *

My peripatetic friend has suggested (Dec. 13) that the surest way to avoid seasickness is to put one eye into retirement. My family has strong Nelsonian traditions, and we have always understood that that great sailor suffered all his life from this distressing disturbance. Does anyone know whether it was less prominent after he lost an eye off Corsica in 1794? But I don't suppose he thought of blocking the contralateral ear, as my colleague recommends. Talking of Nelson, your readers might like to know my personal preference in remedies: I take three grains of phenobarbitone, wrap myself in a blanket, lie down, block both ears, close both eyes, and will the vessel to founder.

Letters to the Editor

PATHOLOGY IN THE NATIONAL HEALTH SERVICE

SIR,—Since its foundation twenty-one years ago the Association of Clinical Pathologists has kept a close watch on the development of the nation's service in clinical pathology, and it may claim to have played some part in shaping it. As officers of the association we should like to assure Dr. Coghill, Dr. Spence, and Mr. Stern that there is no project on the part of anyone to organise "hospital pathology separately from the rest of the professional hospital services." Such a step would, as they rightly point out, inevitably divorce clinical medicine from pathology; and it would be directly contrary to the policy of our association which would have offered to it the most vigorous opposition: fortunately we know that no separation of clinical (which includes hospital) pathology from clinical medicine is in contemplation. We are satisfied that the service in clinical pathology will be developed "as an integral part" of the national hospital service, and further that it will be so developed in close consultation with the pathologists concerned.

So far as hospital pathology is concerned Dr. Coghill and his associates are barking up the wrong tree.

S. C. DYKE
Chairman of Council.
W. H. MCMENEMEY
Secretary, Association of Clinical Pathologists.

HYPERTENSION AND HEREDITY

SIR,—Your interesting annotation of Dec. 6 prompts me to add a few historical facts. The conception of hypertension as a hereditary disease is old. Seventy years ago—that is in the decade preceding von Basch's (1887) introduction of his sphygmomanometer into clinical use—Broadbent, and later Huchard,[1] who was the first to differentiate between two distinct types of hypertension which he termed *artérioscléreux blancs* and *artérioscléreux rouges*, mentioned heredity as the most important ætiological factor. J. Pal (1905) in his *Gefässkrisen* considered hypertension as a "family disease." Alvarez[2] and Vaquez and Leconte[3] took the same view, and Volhard who stressed the point in a paper published by his co-worker John (1913) used—as I well remember from the time I was his assistant in the early 'twenties—to teach his students that it is up to the family doctor to fill the gap in our knowledge about the ætiology of essential hypertension.

Genealogical charts can be traced back to 1899, when Pel[4] published a table of four generations with "chronic nephritis"; this was reproduced in Volhard's monograph[5] which contains family trees covering four generations and gives blood-pressure readings for the last two. Statistical data were given by O'Hare, Walker, and Vickers,[6] who examined the family history of 300 cases of hypertension, with a positive history of vascular disease in 68%, and by Wiechmann and Paal,[7] who in 500 cases found such a history in 38%. But these and other statistics based on circumstantial evidence are not conclusive, since cerebral hæmorrhage and coronary thrombosis are not necessarily connected with high blood-pressure.

There is, however, another more conclusive way to prove the constitutional nature of essential hypertension. In an investigation of the prehypertensive age of descendants of patients with essential hypertension, I frequently found[8] in blood-pressure curves recorded at intervals of under 1 minute up to 1 hour the same huge range of oscillations of the systolic blood-pressure which is

In England Now

A Running Commentary by Peripatetic Correspondents

As soon as Siva appears on the scene, at the Indian Exhibition,[1] stone and bronze begin to dance; they can hardly do less, for he is the Lord of the Dance, the emblem of cosmic rhythm. Symbolic additional arms, weaving into the light-hearted pattern, astound the unaccustomed eye only for a moment; and gods and godlings crowd together, supple as van Gogh's fir tree, until every group seems rustling with movement, or rushing up in flame. How strangely quiet, after this, are the rooms of little brilliant pictures, where flowers enamel the ground and a blue Krishna sports with the milkmaids. They are as bright and vivid as pictures in a missal—

> . . . "Where all is smaller than a wren,
> But has high towers, meteors, and men,
> And suns and spouting whales."

Whales, indeed, are not to be seen, but there are fawns and hounds and horses, and a Persian richness of flowers and trees and shining silks.

* * *

An exhumation I attended a few weeks ago was almost a jolly occasion. Our proceedings started with an excellent cup of coffee and a welcoming smile from a Sister of Charity dressed in flowing black except for her white wimple and a large dangling wooden rosary at her waist. Two of my colleagues were also present—the local medical officer of health, bearing a Home Office exhumation order, and a physician from a neighbouring town, who, like myself, had consented to act as an official medical witness. The morning sun shone into the anteroom while we speculated quietly about our part in the coming ceremony, which had just begun with the chanting of the *Veni Creator* in the adjacent chapel.

Fifty years ago the foundress of the Order, after a saintly life, had died and been interred in a lead coffin in a deep vault beneath the wooden floor of the little church. Convinced of her outstanding sanctity, the community had applied to the Holy See for official inquiries to be made, hoping that these would lead to her beatification. I don't know much about the details except that these inquiries are thorough beyond belief.

First you dig up the body. This had just been done by a small group of blue-overalled workmen, who had torn up the floor, opened the vault, and raised a grimy leaden shell up to floor level and left it by the side of the hole. Seated on a chair in the middle of the little nave was the Reverend Abbot of an adjacent monastery with three or four monks in Benedictine habits, one of whom was the postulator, pressing the cause and acting as master of ceremonies for the occasion. Along one side of the chapel sat a line of nuns of the Order, all Reverend Mothers of branches of the community, some of whom had come half-way across the world to be present. We were given seats opposite the sisters, about three feet from the coffin, around which stood the six workmen. A long trestle table with a heap of rosaries and sacred emblems at one end took up much of the space, and in the background the good nuns had thoughtfully provided several hand basins, hot water, and a large bottle of 'Dettol.'

The Abbot rose and held up a document from the ecclesiastical authorities, the large stone of his finger ring making a touch of colour against the sombre black of his companions. The paper was read, authorising the exhumation and examination of the body, provided that no other bodies were disturbed and that all the process should conform with the laws of the civil authority. Here he turned to the M.O.H. and asked if all was in order to proceed. Receiving an affirmative answer Holy Church got down to serious business. One by one, with their right hands touching a large copy of the Gospels placed in the foreground, the small group of priests bound themselves by a formidable and comprehensive oath to give nothing but true and honest testimony of all that should be seen or found. Then two sisters from the end of the line came forward to be sworn and questioned by the Abbot. They agreed that they had witnessed the interment and that to the best of their knowledge the body had lain there undisturbed for fifty years. Then the chaplain pronounced the solemn curse of excommunication on any person who should, from whatever pious motive, disturb, add to, or remove anything from the coffin about to be opened. Lastly every one of the workmen and we ourselves were sworn in like manner. By this time I felt rather like the Jackdaw of Rheims; and we all know what happened to him.

The foreman of the attendants began work on the shell, introducing the point of a clasp knife into the edge of the lead lid and gently tapping the blade along the whole length of the side to work his way round to the starting-point. He was followed by two of his mates with screwdrivers who gently levered up the small nails securing the lead edges to the wood. The air of expectancy throughout the assembly could almost be felt.

The Roman Catholic Church is not easily persuaded to make new Saints, and first demands overwhelming evidence of their sanctity. I believe that among other things at least two major miracles connected with the Saint must be cited, and the evidence must be faultless and convincing. Later a very sceptical gentleman is briefed as Devil's Advocate and instructed to tear the evidence to shreds. Complete absence of corruption many years after death (embalming and the like being excluded) is a good start, and no doubt many hopeful hearts awaited something of the kind here. It has apparently occurred a good many times in the past. Still we, as doctors and medical sceptics (not to mention our oaths), had no intention of being deceived in any matters to come.

At last the outer lid was prized up and the inner wooden shell revealed with a damp white mould streaking its outer surface. The workmen gently lifted the heavy lid and laid it aside while the foreman easily levered up the light covering of the inner shell lying in a set of grooves. As witnesses we then rose to examine the contents.

Clothed in her black habit and scapular, a small body lay supine, the hands clasping a rosary and a withered spray of flowers, with a faded piece of paper, almost completely decomposed but bearing the faint handwriting of her solemn vows made a hundred years before, between her fingers. From some fault in sealing at the time of burial the coffin was not entirely airtight, and we found the body and outer clothes sodden with moisture. The lining of the shell, the outer clothing, and even the black felt slippers were intact, but the stockings and body covering had almost entirely rotted away. As a whole the body and limbs had retained their normal shape, but the tissues covered by clothes had become converted into adipocere of a white and almost granular consistency. The uncovered face and hands were shrunken and mummified to a brown colour, with the features unrecognisable but the finger-nails intact, though they became detached at a gentle touch.

The quiet voice of the postulator adjured us to make as thorough an examination as possible and to give an exact account of the condition of the body and all the limbs. I called to two of the sisters to free the heavy leather girdle and expose the rest of the body so that I could examine it while my physician colleague took notes. characteristic of the first stage of essential hypertension, then termed by me "chronic intermittent hypertension." These oscillations occur quite independently of the absolute height of the systolic blood-pressure and are present even if symptoms of angioneurosis—the equivalent of essential hypertension in the young—are slight or absent.

Nuneaton. L. HAHN.

TEACHING APPOINTMENTS

SIR,—Dr. Black (Dec. 6) has completely missed the main point of my letter on Nov. 22. I had no desire to belittle the contribution to medicine of laboratory research-workers. The issue is an entirely different one. It is that people who have achieved success as laboratory workers, but who have had extremely little clinical experience, are being given appointments as teachers of clinical medicine. In my opinion—and I am supported by many others—this is wrong, because it is unfair both to clinicians, who have spent years improving their clinical knowledge, and to the great bulk of students.

The position has arisen in large measure from the fact that in the past research-workers were underpaid. With more money, but not enough to employ as teachers both trained clinicians and laboratory research-workers, many of the universities have appointed the latter as more likely to bring fame and honour to the schools; so we may see a university appoint a biochemist as a professor of clinical medicine, and a bacteriologist as the senior lecturer. I feel sure that if that great teacher and clinician, William Osler, were alive and were to apply for the post of senior lecturer in clinical medicine, he would at many schools be turned down in favour of a young fellow who has published some papers on the aluminium content of fluids removed from the nuciform sac.

I am not asking, as Dr. Black suggests, university authorities "to dismiss research ability from their consideration in appointing senior staff." What I am asking is that when they appoint professors and senior lecturers in clinical medicine, clinical experience and ability and an aptitude for teaching, should be the major considerations.

That distinguished teacher and clinician, Dr. F. M. R. Walshe, in his recent address to medical students (*Lancet*, Dec. 6, p. 817), has answered the points raised by Dr. Black. The objects of a teaching hospital are, says Walshe, "to advance knowledge, to train doctors, and to set an example of practice." Further, he points out, clinicians as well as laboratory workers have contributed to this advancement. Doctors cannot "set an example of practice" if they themselves are not good clinicians; and good clinicians are not made in the laboratory. M.R.C.P.

COAGULATION FACTORS

SIR,—I cannot quite agree with Professor Seegers (Nov. 1), who, holding "your leading article on Sept. 13 to be misleading and inaccurate," says: "The account given above records who established these facts."

As I pointed out in my letter earlier this year (June 7), it was Dr. Owren who first proved definitely the existence of at least one more coagulation factor. This factor V, as Owren calls it, is different from prothrombin but absolutely necessary for the conversion of this substance to thrombin by thromboplastin and calcium. This discovery was made in 1943, and a preliminary report of the isolation and properties of the new factor was read before the meeting of the Norwegian Academy of Science in Oslo on Nov. 10, 1944.[1] In this connexion I would recall that Norway at that time was still under German occupation, and that Dr. Owren therefore had no opportunity to publish his findings in an international journal to which other workers in this field had access. Conditions in Norway during and immediately after the war are also to be blamed for the delayed publication of Owren's monograph on the subject, which appeared in 1947.[2] On the other hand, many of the British and American journals were not available in Norway for a long time. Thus, the paper of Professor Quick on prothrombin A and B, published in 1943,[3] did not reach Norway until last year.

What I want to make clear is that the work of Owren has been carried out quite independently, and that it is not, as one might believe on reading Professor Seegers's letter, a mere confirmation of the findings of other investigators. The paper of Fantl and Nance[4] was published at a time when Dr. Owren had given a series of lectures about his factor V in Norway,[5] Denmark,[6] and Sweden[7]; and a few days after its appearance he also lectured in London[8] and Oxford.[9]

The work of Owren brings for the first time into harmony several of the earlier contradictory observations, by showing that the "pure" preparations of coagulation factors used by previous investigators were all contaminated with factor V to a greater or less extent. Factor V is not an accelerator in the strict sense of the word, but a true coagulation factor, for no coagulation takes place (in vitro) in the absence of factor V. Whether factor V itself is able to bring about the transformation of prothrombin into thrombin through the action of thromboplastin and calcium, or whether, as Owren thinks, it first has to be converted into factor VI, which then would be the real coagulation factor, remains an open question. As far as I can see, the prothrombin B of Quick[3] is identical with what Seegers and Owren more correctly call prothrombin, while prothrombin A and the accelerator substance of Fantl and Nance and of Ware, Guest, and Seegers[10] is identical with factor V.

I hope that these remarks may help to remove some of the mist that seems to make it difficult to discover "who established these facts."

Hospital, Oslo, Norway. KARL CLOSS.

BREACH OF CONFIDENCE?

SIR,—I cannot help thinking that the profession is unaware in how many ways breach of medical traditions is occasioned by the procedure adopted by the Ministry of Food in enlisting the support of their so-called "medical advisers" to override medical certificates which medical practitioners are required to send to the Ministry of Food when requesting allowance of special invalid diets. The procedure was described very fully in an important debate (*Hansard*, Jan. 22, 1947), and it was condemned from all parts of the House.

The doctor is required to submit a medical certificate, describing in great detail the character and prognosis of the illness for which concession is asked. Unless the illness fits into a schedule of diseases furnished by the medical advisors as automatically deserving priorities—in which case the concession is automatically made—the Minister of Food's clerks, on their own responsibility, select that one of the medical advisers whom they consider proper to approach in the case. If such a position arises, a bunch of civil servants, with no medical knowledge or experience, presume to sit in judgment upon certificates furnished by registered medical practitioners in actual charge of the patients concerned, and these certificates may be overruled by some unnamed medical practitioner who has had no contact with the patient, who may have had no experience of the specific illness, and who certainly has no knowledge whatever of the individual circumstances of the case.

I submit, Sir, that this procedure involves the negation of well-established rules of professional conduct, some based on immemorial sanctions.

1. A medical certificate, which should enjoy the fullest protection of professional secrecy, is submitted without the authority of the patient to lay inspection, which may in certain circumstances involve publication even more wide than that of the Ministry's clerks. I have before me a letter from a distinguished medical practitioner, who found that

his certificate, sent to the Minister. in which he had expressed the opinion that the patient would probably die had been communicated to a food office in the district where the practitioner practised, and he learned that certain district nurses were discussing the probability of this patient's death, having obtained this information via the local food office. At the recent session of the General Medical Council the chief medical officer to an Irish insurance company was adjudged "guilty of infamous conduct in a professional respect" for having sought from a registered medical practitioner information regarding his patient, who had not authorised such disclosure. The chairman, in giving judgment, said that the Council "took a very serious view of any action which might impair the patient's trust in the confidential nature of any information obtained by a medical attendant about his patient."

2 The medical advisers, or some of them. are offending against the salutary rule that a medical certificate should not be given without proper medical examination of the patient immediately prior to the issue of the certificate. When the General Medical Council met last month a medical practitioner was severely censured, and narrowly escaped removal of his name from the Register, because he had given certificates which sought out of compassion to prolong for a short time the leave of a serving soldier whose father had been under the practitioner's medical care two or three weeks previously, but not immediately before the certificates were issued. These certificates declared that the father was ill enough to require his son's aid.

3. Modern medicine deprecates a philosophy which regards diseases as entities. The wiser conception is surely that of a sick person who shows symptoms which, for convenience, may be grouped as a syndrome, but exhibiting individual differences which require individual treatment. It is the flouting of such a conception which fosters the wicked racketeering by the patent-medicine trade, with its lists of diseases, each calling for such-and-such a nostrum.

I submit that it is in the highest degree regrettable that the "medical advisers" who enjoy the prestige of membership of the Medical Research Council should lend their support to practices so repugnant to medical science and to medical ethics.

House of Commons. E. GRAHAM-LITTLE.

A SIMPLIFIED ANATOMICAL NOMENCLATURE

SIR,—Some day within the next decade or two the medical course will have to be extended considerably unless the annual growth of the syllabus is curtailed. There is one sphere in which this could be done without loss and even with profit—namely, anatomy. For instance, the index of *Gray's Anatomy* lists about 380 named arteries and a corresponding number of veins. I wish to put forward a scheme for reducing this number considerably while at the same time making it easier to picture the course of a vessel in relation to the whole body.

The adult arterial system consists essentially of a dorsal aorta with a bifurcation at each end. Let us term the two cranial branches *directly* the right and left subclavians, and let us say that they extend down to the elbow, having passed through the axillary fossa and curved round to the front of the arm when the palm is uppermost. At the lower border of the elbow-joint they bifurcate to give us the anterior and posterior subclavian branches, while from the posterior branch just after its origin there arises the anterior interosseous which in turn gives off the posterior interosseous. The anterior subclavian continues down to supply the thumb and by the palmar ramification an anastomosis is formed between anterior and posterior subclavians. That is a comprehensive and easily retained picture: the subclavian arising from the aortic arch and reaching to the finger tips.

Similarly the caudal fork can be dealt with. To correspond as closely as possible with the upper part of the body let us call the single vessel that reaches from the fourth lumbar vertebra to the back of the knee the femoral artery. Then the aorta divides into the right and left femoral arteries from which are given off the right and left iliacs. The femorals pass down through the femoral triangle and run down in an elongated spiral, medially directed, to reach the popliteal fossa at the back of the knee-joint, after which they divide into anterior and posterior branches, the posterior in turn giving off the peroneal. At the foot the posterior branch divides into lateral and medial plantar, ramifying round the toes where an anastomosis is effected with the arcuate ramification of the anterior femoral artery.

Admittedly this is only the barest outline, and an extensive filling-in is needed; but, even so, a person with no special knowledge of anatomy could draw an accurate diagram of the major vessels as the description was read to him. The same treatment can be applied to many of the branch arteries. Why, for instance, complicate the internal iliac by naming its divisions anterior and posterior rami which become the inferior and superior gluteal? Why not call them by the name gluteal at once?

Surely the very naming of an artery "innominate" shows that the nomenclature had defeat within itself, even while developing towards its present complexity.

Trinity College, Dublin. MICHAEL DILLON.

⁂ Anatomical nomenclature badly needs simplifying, and our correspondent's proposals are attractive. But extending names to cover such long tracts of vessels and nerves would make it difficult to specify particular parts of the tracts. It would also create confusion for comparative anatomists unless it were applied throughout the vertebrate phylum.—ED. L.

DIABETIC ARTHROPATHY

SIR,—In his letter of Nov. 15 Dr. Shore described a Charcot knee-joint in a diabetic. Several similar cases have recently been reported, but in most of these the ankle-joint was affected. Rundles [1] describes one case with extensive disruption of the tarsometatarsal joint, with loss of joint surfaces and many loose bodies. Fourteen diabetic cases seen at the New England Deaconess Hospital had suffered painless destruction of joints of the tarsus during the previous few years [2]; and Jordan [3] gives details of a woman with diabetes of 14 years' duration who developed a typical painless Charcot joint of the ankle; in addition to chronic osteomyelitis of the foot of an unusual type and without obvious ætiology. Later he [4] reported two further cases of diabetes—one with a neuropathic ankle-joint, and the other with changes in the lumbar vertebræ. As Dr. Shore mentioned, Foster and Bassett [5] have published the histories of two cases of severe, poorly regulated diabetes in young men, complicated by a Charcot ankle-joint.

The following case at present under observation in our diabetic clinic seems worth describing.

A clerk, aged 62, was first seen in January, 1939, with a four weeks' history of thirst, polyuria, and loss of weight. At that time no abnormal signs were discovered in the central nervous system; he was treated by diet alone, and his symptoms rapidly subsided. When complaining of chronic pains in his limbs in June, 1942, the knee and ankle jerks were found to be absent, and treatment with insulin was started. About a year later, because of diarrhœa the dose of insulin had to be reduced. In November, 1943, he developed acute iridocyclitis, and in 1944 he was treated for trophic ulcerations on the right leg; there were then signs of peripheral neuritis: the Wassermann reaction (W.R.) was negative. During 1945 he complained of giddiness and deafness and was found at times to have a fine nystagmus which, it was suggested after full examination, was due to toxic neuritis of the right auditory nerve. The blood W.R. was again negative. The cerebrospinal fluid (C.S.F.) contained no cells and 50 mg. of protein per 100 ml.; the test for excess globulin was negative as was the W.R.

In October, 1946, without antecedent trauma, the patient suddenly began to have severe pain in his left knee which was swollen and hot, though only osteoarthritis with some osteoporosis was revealed by radiography. Two months later, however, further X-ray films showed a pathological fracture at the upper and inner border of the left tibia, with marked bone sclerosis and new bone formation. Although then

2. Bailey, C. C., Root, H. F. *J. clin. Invest.* 1942, 21, 649.
3. Jordan, W. R. *Arch. intern. Med.* 1936, 57, 307.
4. Jordan, W. R. *Sth. med. J.* 1943, 36, 45.
5. Foster, D. B., Bassett, R. C. *Arch. Neurol. Psychiat.* 1947, 57, 173.

tender, the joint has since become painless, but has remained grossly swollen; and it is now completely disorganised. Full examination at that time revealed small irregular pupils irresponsive to light and convergence; almost complete loss of vision due to bilateral cataracts; loss of all tendon-reflexes but brisk abdominal reflexes; and diminished cutaneous sensibility in "glove-and-stocking" areas. Ataxia and incoördination were not pronounced; there was generalised muscular wasting of the legs with loss of power, but no gross hypotonia or muscle tenderness. The C.S.F. examination was repeated with a similar result except that the globulin reaction was positive; but the colloidal-gold curve was 0000000000. The W.R. was again negative in both blood and C.S.F.

It has been suggested that this in fact is a case of tabes dorsalis complicated by diabetes; but the loss of pupil reaction can be explained on the history of diabetic iritis and keratitis, and in the absence of historical, clinical, or serological evidence of syphilis, a diagnosis of diabetic arthropathy appears justifiable.

My thanks are due to Dr. H. K. Goadby, who is in charge of St. Thomas's Hospital diabetic clinic, for permission to publish the above case.

St. Thomas's Hospital, London, S.E.1. G. E. SPEAR
Medical Registrar.

PENICILLIN BY MOUTH

SIR,—I read with great interest the excellent article by Dr. Stewart and Dr. May in the issue of Dec. 13. This investigation has been wanted ever since the introduction of penicillin therapy. I wish to add a rather modest contribution to their findings.

I have used penicillin by mouth for the last twelve months in chronic wards. I was prompted to oral administration of penicillin by: (1) the natural aversion of elderly patients to needling; (2) the effectiveness of this route in children: and (3) American publications. I have used it in various conditions such as urinary infections, respiratory infections, bedsores, and skin infections; at first I was surprised by its beneficial effect but later was surprised if it failed. I ascribed the failures to penicillin-insensitive organisms and to the feeble circulation in greatly debilitated chronically ill or very old people. No doubt some of my failures must have been "poor absorbers"; and possibly the dosage was inadequate.

I gave 500,000 units twice daily: the first dose approximately two hours after breakfast, and the second two hours after tea. I used both yellow and white penicillin diluted in 10 ml. of distilled water. The complications I met were stomatitis during penicillin treatment in 2 cases, and in 1 case an urticarial rash with giant weals ten days after cessation of treatment. However, this last patient was treated concurrently with sulphadiazine, and one and three days before the appearance of the rash he had two sittings of ultraviolet-light treatment. Thus, I rather hesitate to blame the penicillin for the rash.

Joyce Green Hospital, Dartford. E. GANCZ.

VIABILITY OF TREPONEMA PALLIDUM

SIR,—Readers of Dr. Lumsden's article on the above subject, in your issue of Dec. 6, may be interested in an experiment which I carried out in 1933, in collaboration with Dr. McNabb, Dr. Matthews, and Dr. McClure of the Toronto Public Health Laboratory. This was reported in the *Bulletin of Hygiene* [1] (in reviewing a paper by these authors [2] on a combined outfit for collection, in capillary tubes, of specimens in the field); it was also mentioned in a letter to THE LANCET.[3] Briefly, the Canadian workers sent me six outfits for collection of specimens for dark-ground examination, and these were filled in the V.D. department, St. Thomas's Hospital. On arrival in Toronto, the contained specimens of *Treponema pallidum* were found to be still motile. Three of the tubes were returned to me with another collected in Toronto. The contained *T. pallida* were still motile, and the preparations of them, each now between slide and cover-slip luted with wax, were returned to Toronto. They were reported to be still motile there and were returned to me. In London motility continued for four days after receipt. Thus three of the specimens crossed the Atlantic four times and the fourth three times; the intervals from the taking of the specimens to final disappearance of motility were, 84, 75, 72, and 50 days. The persistence of motility after the third journey was confirmed by the Toronto workers and after the fourth by those in my clinic.

London, S.W.1. L. W. HARRISON.

BLOOD SAMPLES FROM INFANTS

SIR,—Blood may be collected from infants under 12–18 months of age from the anterior fontanelle, the heel, the jugular vein, or the great toe. To obtain 5–10 c.cm for serological tests is not always as easy as in an adult. Recently I had occasion to take samples from a series of 150 infants and found the great toe a convenient site to use.

The patient's right leg (if the doctor is right-handed) is bathed for ten minutes in warm water; it is dried and a crêpe bandage firmly applied from the ankle to above the knee. The nurse then holds the baby so that its right foot rests between the operator's knees, while the foot, after sterilisation with methylated ether, is firmly grasped in the left hand and the great toe steadied. Using a Graefe's cataract knife, an incision about $^1/_8$ in. long and $^1/_{10}$ in. deep is made on the internal aspect of the toe parallel with its long axis. The crêpe bandage is relaxed and the toe slowly rotated clockwise through an angle of 45° with a firm grip. The grip is then relaxed and the toe released. As this movement is repeated, the incision automatically opens and a wave of blood flows down the inside of the foot and can be collected to the desired amount.

If the foot is held firmly and the incision made rapidly it is surprising how little evidence of pain is registered by the patient—little girls especially being apparently more curious than hurt by the whole procedure. When sufficient blood has been collected the flow is stopped by firm pressure with cotton wool for 30 sec. and a small elastic adhesive dressing applied immediately. This, in all cases, was sufficient to arrest the bleeding and secure healing by first intention.

Manchester. ANDREW V. MAGEE.

Parliament

FROM THE PRESS GALLERY

Medical Practitioners and Pharmacists Bill

ON Dec. 16 the House of Lords agreed to the Commons amendments to this Bill.

QUESTION TIME

Fowl Pest

SIR J. BARLOW asked the *Minister of Agriculture* how many cases of fowl pest there had been in each of the last six months; and what precautions were being taken to combat this disease.—Mr. T. WILLIAMS replied: The figures for June to November are 209, 112, 62, 145, 539, and 665 respectively. I have made an order prohibiting in certain circumstances the sale, movement, and gathering of live poultry in England and Wales. The importation of dead poultry from countries in which the disease exists is prohibited, and the importation of dead poultry from Europe is limited to eviscerated carcases. There has been some diminution in the spread of the disease since the beginning of this month—98 outbreaks were reported from Dec. 1 to 11, compared with 276 for the corresponding period in November.

Sir J. BARLOW: Is the Minister aware that certain expert opinion is that this disease is transmitted to poultry in the marrow of bones so that the importation of drawn poultry does not entirely meet the case?—Mr. WILLIAMS: We got all our advice from our experts and we act accordingly.

THE title and status of emeritus professor of medicine of the University of Athens has been awarded to Dr. A. P. Cawadias by royal Hellenic decree.

THE Royal Society has appointed Dr. G. S. Dawes, of Worcester College, Oxford, to a Foulerton research fellowship in medicine.

Obituary

BERNARD SPILSBURY

KT., M.A., B.M. OXFD, F.R.C.P.

ENGLISH forensic medicine has lost a commanding figure in the death of Sir Bernard Spilsbury on Dec. 17 at the age of 70. For thirty years he had stood alone and unchallenged as our outstanding medicolegal expert, achieving both public and academic distinction and earning by his conscientious application and integrity the high regard of his own critical profession.

Educated at University College School, Manchester Grammar School, Magdalen College, Oxford, and St. Mary's Hospital, he was trained in bacteriological work as a member of Sir Almroth Wright's team at St. Mary's, but towards the end of King Edward VII's reign he set out on his career as a morbid anatomist and histologist, holding posts in these branches of medicine for many years at both St. Mary's and St. Bartholomew's Hospitals, and relinquishing them only because of increasingly heavy calls on his services as a forensic expert. He had a flair for simple exposition, and his painstaking search for evidence, together with his gift for evaluation and reasonable inference, quickly proved their usefulness to the police. To these basic qualities he added an honesty of purpose and a personal integrity that was never questioned: he provided a pillar of security in the medical evidence for Crown prosecutions in crime. Once Spilsbury had made up his mind he adhered to his views inflexibly, immune alike to assault and to the blandishments of flattery. He was indeed a master of the art of plain unvarnished reasoning; and both time and the circumstantial evidence bore out his soundness in case after case from the time of Crippen to that of the bandit murdering of Antiquis.

Topical Press Agency

He achieved in turn acknowledged leadership in his profession, academic lectureships, examinerships at Oxford and London, Home Office approval, a knighthood (in 1923), fellowship of the Royal College of Physicians, and presidency of the Medico-Legal Society—all with the same apparent imperturbability and the same secret pride, unaffected yet aware of his qualities of leadership in a previously unled profession. His natural reserve was never overcome and he remained humble with his own conscience, strange and unacceptable as this may seem to those who merely saw but did not know him. His assurance in the witness-box misled the public into the belief that he had become a witness for the prosecution; but there were occasions when his prescience dissipated suspicion and freed an innocent prisoner.

Spilsbury spent many hours and much tedious work in making up his mind: he wrote elaborate notes and longhand reports. But, despite his stubborn resistance to any effort to shake his belief in what he had determined was the truth, he remained impartial and scientifically reasonable, difficult to tilt, aloof and a little cold, but prepared to accept challenge even if he did not welcome it. No practitioner worked harder; he never failed to visit the scene of a crime, town or country, day or night, and never failed to be at hand at the trial, ready to accept reason or rebut the unacceptable. Fees were of no great importance to him, and indeed his disinterest in money limited both his leisure and his material relaxations. As a lecturer he shone less brilliantly, disliking routine teaching, writing but little and lecturing even less outside his three London school appointments—St. Thomas's, University College, and the Royal Free. Retiring and outwardly frigid, he disliked visits from strangers and seemed somewhat distant to casual professional acquaintances. In reality he was a lonely man, an idealist in plan, compromising in practice, relaxing little. He overtaxed his failing health and was sadly stricken by the loss of two of his three sons, fading finally to a figure which, though it never lost respect, became too frail for this hard world. He will remain a revered figure in medicine.

HAMISH FALCONER MASSON

M.A., M.B. EDIN., F.R.C.S.E.

Dr. H. F. Masson, who died on Dec. 7 at the age of 45, was the third son of the late George Masson, J.P., of Kingussie. He was educated at Fettes College and Edinburgh University, where he took a classical M.A. in 1932, and three years later his M.B. After holding house-appointments at Preston Royal Infirmary and Kettering General Hospital he took his F.R.C.S.E. in 1930. For a time he was in practice in Dingwall before settling in South Woodford, where he had practised for the last ten years.

"Hamish Masson," writes J. B. Y., "had intellectual gifts that could have carried him to a high place amongst consultants, but he preferred general practice with its more personal human contacts. His handsome appearance and attractive personality made him a conspicuous figure in any company, but no man so gifted was ever more unassuming, or more tolerant towards his fellow men. His work made great demands upon him, and he never spared himself. In the last year his health gave some grounds for anxiety, but the end, when it came, was unexpected."

Dr. Masson, who married only eighteen months ago, leaves his widow with a young son.

DOUGLAS ARTHUR CLOUSTON McRAE

M.B. EDIN., M.R.C.P.E.

Dr. D. A. C. McRae, director of the blood-transfusion services for South-east Scotland, who died recently in Edinburgh, graduated M.B. at Edinburgh in 1938. After qualifying he held house-appointments at the Edinburgh Royal Infirmary, where he later became clinical tutor. McRae was a former president of the Royal Medical Society, and one of his contemporaries writes: "He was the most brilliant man of his year, although no academic honours came his way as an undergraduate, for his intellectual energies were spent in many and diverse channels—the Bach Society and Palestrina Club were only two of his cultural activities. A man of infinite charm, he leaves nothing but pleasant memories for those who knew him well."

HENRY COOPER

D.S.O., M.A. CAMB., M.R.C.S.

Group-Captain Henry Cooper, who died on Dec. 13, was one of the pioneers who, at the end of the 1914–18 war, were responsible for the formation of the medical service of the Royal Air-Force.

Born in 1877, the second son of John Spyvee Cooper, of Hull and Windermere, he was educated at Denstone College and Emmanuel College, Cambridge, where he took the natural sciences tripos in 1899. From Cambridge he went to the London Hospital, and after qualifying in 1904 he entered the Royal Navy. During his service in the Mediterranean he was present at the fall of Salonika, and he was in Constantinople during the Balkan war. In 1914–18 he served ashore in France and Belgium with the R.N.A.S. and armoured cars, receiving the D.S.O. and being appointed an officer of the Crown of Belgium for his distinguished and gallant conduct. With the formation of the Royal Air Force in 1918 he transferred to the new Service, and he was one of the small company under Sir Matthew Fell who started its medical branch. As may be imagined, this was a period bristling with difficulties, which provided wide opportunities for Cooper's organising abilities, inexhaustible tact, patience, and kindliness. On leaving the Air Ministry in the early days of the new Service he went to India as principal medical officer, R.A.F., whence he was posted to Iraq in a similar capacity, where he dealt competently with an epidemic of cholera. On his return to this country he was appointed P.M.O., Air Defences of Great Britain. From 1930 to 1932 he was honorary surgeon to the King.

After he retired in 1932, Cooper became clerk and registrar to the Society of Apothecaries, and the ancient hall of the society and its contents were a never-ending delight to his sense of history. When war broke out in 1939, though long past the age of recall, he volunteered for service and became P.M.O., Balloon Command, and from 1942 to 1945 he served at the Ministry of Health as assistant director of personnel in the E.M.S.

In 1906 he married Miss Grace Shone, who survives him with one daughter.

HERBERT THOMAS HERRING

O.B.E., M.B. DURH.

Dr. H. T. Herring, who died in London on Nov. 22, received his medical education at University College, London, and at Newcastle-on-Tyne. He took the Conjoint qualification and his M.B. Durh. in 1887 and he held a house-appointment at University College Hospital. Setting up in practice in Weymouth Street and later in Harley Street he followed Buckston Browne as assistant to Henry Thompson. At that time, before the advent of prostatectomy, the only method of relieving obstruction was by catheterisation, and as this had to be carried on indefinitely, asepsis was of vital importance. Herring devoted all his ingenuity to perfecting his technique, and was so successful that he was able to catheterise patients for years without producing cystitis. He published in both English and German his method of sterilising catheters, besides a considerable number of other communications based on a large urological experience. He was probably the last surgeon in this country to pass a catheter with the patient standing erect, his back pressed firmly against a velvet-covered area on the wall of the consulting-room. It is a method now forgotten, which is much simpler to use than one would imagine. The late Sir Peter Freyer once demonstrated it to an interested group at St. Peter's Hospital, and in his hands it seemed easy.

Through Sir Henry Thompson, Dr. Herring became interested in cremation, and served as honorary secretary of the Cremation Society, medical referee to the Woking crematorium, managing director of the Woking and Golders Green Crematoria, and honorary treasurer of the International Cremation Federation. In the later years of his life he set out daily from his home in Harley Street to the Cremation Society's offices in Baker Street, and in name and person he became well known to a large circle of doctors who sought the society's help.

THE LATE DR. BOLTON

Mr. F. J. M. Barrington writes: Though known best to most of his acquaintances as a physician of unusually sound judgment, the most remarkable feature of Charles Bolton's life was probably that he continued doing experimental research not only after he had a busy practice but even after he had retired from his hospital's staff. In fact he only stopped this when prevented by ill health. When he was director of the Graham research laboratories of University College Hospital medical school from 1908 to 1914, the people working there were nearly all trying to do something different, according to their interests, with the result that the possibility of any "direction" was slight. In spite of this he generally seemed to know what everyone was doing, and whether it was likely to lead to any good or not. A result of this circumstance was that he had more time for his own experiments, and in these years he probably did more than at any other time, chiefly on the production and absorption of lymph and on the healing of acute gastric ulcers. He was an exceptionally dextrous operator.

JAN MAZURKIEWICZ

Dr. J. Leyberg writes: Professor Mazurkiewicz, director of the psychiatric clinic at Warsaw University, died in Warsaw on Oct. 31. For many years president of the Polish Psychiatric Association, he was the most outstanding psychiatrist in the country. His organic approach to psychiatry was profoundly influenced by the writings of Pavlov, Sherrington, Adrian, and Hughlings Jackson, and his lectures enabled many Polish graduates to become acquainted with the British school of neurophysiology. During the German occupation he wrote a book on Evolution and Dissociation in the Central Nervous System, which is to appear shortly. His death will be sadly felt in Poland, particularly by those who had the privilege of working under his wise and friendly guidance.

Births, Marriages, and Deaths

BIRTHS

BUKY.—On Dec. 15, in London, the wife of Dr. W. W. Buky—a son.

CORMAC.—On Dec. 6, at Stockport, the wife of Dr. C. D. Cormac—a daughter.

DORNHORST.—On Dec. 15, in London, the wife of Dr. A. C. Dornhorst—a daughter.

DOWLING.—On Dec. 15, in London, the wife of Dr. M. A. C. Dowling—a son.

GAULD.—On Dec. 14, in London, the wife of Dr. G. O. Gauld—a son.

KENIG.—On Dec. 11, in London, the wife of Dr. M. Kenig—a son.

KING.—On Nov. 10, at Klagenfurt, Austria, the wife of Lieut. Colonel Cecil King, R.A.M.C.—a daughter.

LONGRIDGE.—On Dec. 12, at Salisbury, the wife of Dr. R. G. M Longridge—a son.

MACKAY-DICK.—On Dec. 4, at Wuppertal, Germany, the wife of Lieut.-Colonel John Mackay-Dick, R.A.M.C.—a daughter.

MACKENZIE.—On Dec. 12, in London, the wife of Dr. A. G. Mackenzie—a daughter.

NIBLOCK.—On Dec. 7, at Peshawar, Pakistan, the wife of Major W. McN. Niblock, F.R.C.S.—a son.

PRICE.—On Dec. 10, to Dr. Celia Westropp and Francis Price—twin sons.

PRITCHARD.—On Dec. 14, at Chobham, Surrey, the wife of Dr. P. M. M. Pritchard—a daughter.

WATSON.—On Dec. 10, at Devizes, the wife of Dr. R. W. Watson—a son.

WHEATE.—On Dec. 10, in London, the wife of Dr. H. W. Wheate—a son.

MARRIAGES

MURPHIE—LINDOW.—On Nov. 29, in London, Charles Ian Murphie B.M., to Elizabeth Anne Lindow.

STONE—SIMPSON.—On Dec. 13, in London, Patrick Stone, M.B., to Elisabeth Moone Simpson.

WOODYATT—PARBERY.—On Dec. 10, in London, Peter Bruce Woodyatt, M.R.C.S., to *Elaine Joan Parbery.*

DEATHS

COOPER.—On Dec. 13, in London, Henry Cooper, D.S.O., M.A. Camb., M.R.C.S., group-captain, R.A.F.

CURPHEY.—On Dec. 12, at Bath, Elizabeth Curphey, B.SC. Lond., M.R.C.S.

DOWLING.—On Dec. 15, at Preston, Lancs, Edward Dowling, B.A., M.D. R.U.I.

FINDLAY.—On Dec. 13, in Edinburgh, James Findlay, M.A., M.B. Glasg., lieut.-colonel, I.M.S. retd.,

FREETH.—On Dec. 16, Arthur Causton Freeth, M.B. Durh., aged 57.

JOHNSTON.—On Dec. 15, at Prestatyn, Francis Johnston, M.B. Glasg., aged 89.

MILLIGAN.—On Dec. 11, at Guildford, James Knowles Milligan, M.R.C.S., aged 65.

SPILSBURY.—On Dec. 17, in London, Bernard Henry Spilsbury, Kt. M.A., B.M. Oxfd, F.R.C.P.

STEWART.—On Dec. 8, at Gerrards Cross, Bucks, Rothesay Charles Stewart, M.R.C.S.

WOOLLEY.—On Dec. 16, at Hove, Jasper Maxwell Woolley, M.D. Camb., D.P.H., lieut.-colonel, I.M.S. retd.

Notes and News

THE TAVISTOCK CLINIC

LAST year the professional committee appointed to consider the rôle of the Tavistock Clinic in the post-war world, and the ways in which its work in social psychiatry might be extended, made two important decisions [1]—that the assets of the clinic should be spent on anticipated costs up to the day when it will be handed over to the Ministry under the National Health Service, and that the Institute of Human Relations should be legally separated from the clinic so that it may continue its independent work in fields not covered by the N.H.S.

The clinic and institute are organised on a practical plan: all members of the staff belong to work-groups known as units, with the coördination unit acting as a secretariat to the others. A senior member of the full-time staff, who is also on the professional committee, is responsible for one or more of these units, and these members also form the management committee of both clinic and institute. Each unit carries out projects in its own field but also contributes to training and research. At present, besides the coördination unit, there are an adult unit and a child-guidance unit. The adult unit offers to patients a consultation and counselling service, and a treatment service. Some patients require individual therapy for longer or shorter periods, but others can be helped considerably in group discussions.

The Institute of Human Relations, in a statement of aims and policy, is described as an attempt to develop a scientific institution equipped to respond to practical social demands such as problems of industrial morale, in new communities and in many aspects of education and family life. It undertakes work arising out of specific requests for help, and gives full technical collaboration to all concerned with a particular problem—assuming joint responsibility in working things out to a satisfactory finish, rather than giving an "expert opinion" and retiring from the field. Like the clinic, the institute is a federation of units, and these cover industrial projects, social and cultural projects, and educational projects: a fourth unit is responsible for publications, among which is a quarterly journal, *Human Relations*. The research programme includes accurate assessment of work done, and the development of new methods, especially with group technique and the study of "group dynamics." Group treatment of psychiatric patients, group discussion methods for education and training, and group techniques for such special purposes as leadership training and personnel selection are being studied. It is also hoped to develop new means of appraising personality and intelligence, and of treating speech disorders, and to study the causes, prevention, and treatment of delinquency.

WORK FOR THE BLIND

THE wide scope of the work of the National Institute for the Blind shows how much generous sympathy blindness excites, and to what practical use it can be put. The report for 1946–47 says that, besides an educational programme for children from birth to school-leaving age, the institute has two schools for adults—a school of physiotherapy and a school of telephony. At the school of physiotherapy, Great Portland Street, 40 students are in training, both blind civilians and ex-Service men and women, and there are increasing numbers of applications for places from the Dominions. During the year, 21 new trainees entered the school of telephony at Bridgnorth.

The Queen Elizabeth Homes of Recovery—America Lodge, Torquay, and Long Meadow at Goring-on-Thames—are centres for the training and reinstatement of the newly blind. Newcomers, removed from the fussy commiseration of relatives, find themselves among others who have mastered their disability. Their seemingly casual welcome is carefully planned, and they quickly find themselves sharing in a full and active life—learning Braille, Moon, and typing; trying their hands at woodwork and pottery; visiting cinema and theatre; taking part in dances and concerts; playing cards, draughts, chess, dominoes, and darts; bathing, rowing, and riding horses—and learning all the time to observe and judge distance by sound.

Since 1943 the placement section has found work in industry for over 700 blind men and women; and though some of these lost their work during the change over to peace conditions, over 600 kept their jobs, and a further 178 have been found work in the past year. A subcommittee on professional placement looks after the interests of blind professional people; and a permanent subcommittee does its best to help blind men with a strong sense of vocation to join the clergy and to carry out their duties effectively. Much of the work of the institute itself is done by blind people, and this is greatly encouraging to those newly blind who come to discuss their problems. "When a newly blind person finds that his phone call for an appointment is answered by a blind operator, that he is interviewed by a blind adviser with a blind stenographer at his elbow, that a blind guide conducts him round the building and shows him blind secretaries, blind transcribers, blind proof-readers, blind writers, blind typists, blind lecturers, blind musicians, blind physiotherapists, blind students at work, and that, to crown it all, a blind man, without a guide, puts him on the right bus for home, then he must feel encouraged. . . ."

The publication of Braille and Moon books, newspapers, and other periodicals is up to the pre-war level, but any increase in scope must depend on better supplies of paper. New premises have been found for the sound-recording studio for talking books, and new talking-book machines are being steadily acquired and supplied to users; but like all other equipment and appliances needed by the blind, they are still scarce.

GROWTH OF PART-TIME NURSING

ON Sept. 30 there were 17,257 part-time members of the nursing and midwifery staffs in our hospitals and other services. According to a report recently presented to the National Advisory Council on Nursing and Midwifery, this shows an increase of about 12,200 on the numbers of part-timers employed nine months before. The growing numbers have meant that waiting-lists for hospital beds, especially for chronic patients, have been greatly reduced, and in some areas have even disappeared. Many regions are now following the successful lead of Gloucestershire and Wiltshire, and the council consider that part-time schemes could be even more widely and thoroughly developed.

FAILURE AS A FAMILY

THE British Social Hygiene Council [1] is now publishing "occasional papers," of which the second is "Problem Families," [2] by Dr. C. Fraser Brockington. The common denominator of these families is that they are "unable by their own efforts to raise themselves from the state into which they have fallen." Dr. Brockington feels that existing social measures do not meet their needs, for the laws protecting children require that they should be removed from the family and placed in different surroundings, whereas the real need is for family regeneration. Moreover, in such problem families there are often strong ties of affection, and parents and children alike suffer when they are separated. He wishes to see a system of "family probation" introduced, problem families being registered as such and placed under the care of local authorities for rehabilitation. Arguments against registration will come readily to mind,[3] but all will agree with Dr. Brockington that it is more liberal to keep the family together (perhaps even at the cost of registration) and to attempt their regeneration as a group, than to compel them to separate. A possibility which he mentions—that of providing hostels where refractory or incompetent mothers can be given training—is already being tried by the Society of Friends.[4]

Dr. W. F. Roper, in "When the Family Fails," [5] discusses the process of socialisation, which, he says, calls for "the gradual interposing between the child and the gratification of his desires of the requirement that he shall secure what he wants by socially desirable means." This is what the family normally achieves, but when it fails the child may grow into the unsocial, the neurotic, or the criminal adult; and what is worse, will repeat his own faulty training in bringing up his family. Dr. Roper hazards a guess at the size of the problem: each year some 80,000 people in Great Britain

commit indictable offences, and a quarter of these are reconvicted within five years; there is evidence that some 5% of the adult population—and this is very likely an under-estimate—are adversely affected by neurotic symptoms; and he puts the proportion of the "ill-conditioned"—aggressive, acquisitive, selfish, and censorious people who work against the best interests of society—at about 10%. Thus, at least a quarter of the population would have benefited by being better brought up. He sees four main lines of prevention: improved economic status of families will remove one incentive towards selfish and acquisitive impulses; treatment of the ill-conditioned in prison, clinic, school, and institution may help to make better parents of them, and so benefit the new generation; family can help family in associations like the Peckham Health Centre; and propaganda will wake interest and spread knowledge. Finally, research alone can teach us more about the results of family failure and the remedies for it.

HONG-KONG'S HEALTH

NINE months ago we reviewed[1] the official report of Hong-Kong's war-time privations. The latest report[2]—that for 1946—is the last to be made by Dr. P. S. Selwyn-Clarke as director of Hong-Kong's medical services, before his appointment as governor and commander-in-chief, Seychelles. The statistics for last year give little hint of the hard years that went before. The infant-mortality rate was a third of that in 1940 and a sixth of that in 1931; while the death-rate (56·9 per 1000 in 1940) fell to 14·2. The report observes that two theories have been advanced in explanation of this fall: one is that the weaker went to the wall under the rigorous siege conditions; and the other is that the partial replacement of rice by flour has made for a better-balanced diet, with a lowered incidence of beriberi and other nutritional diseases.

University of Oxford

On Dec. 13 the degree of D.SC. was conferred on Mr. J. Walker, PH.D., a member of the scientific staff of the Medical Research Council in the chemotherapy department of the National Institute.

University of Manchester

At recent examinations the following were successful:

Final M.B. and Ch.B. Examination.—Mary K. Astin, Anthony Condy, M. B. Edwards, D. D. Hilton, R. A. Kershaw, Alwyn Kinsey, C. I. Moss, Raymond Ormerod, J. E. Parry, F. A. Rainford, O. R. W. Sejrup, Bernard Stone, Margaret E. Thorp, R. J. A. Webb, H. W. Wilson, Peter Wolf, D. H. Wright.

D.P.M. (*part II*).—George Christie, Frank Howarth, Helen E. Smith.

Royal College of Physicians of London

On Tuesday and Thursday, Feb. 10 and 12, at 5 P.M., Prof. G. S. Wilson will deliver the Milroy lectures at the college, Pall Mall East, S.W.1. He is to speak on the Public Health Laboratory Service.

Royal College of Surgeons of England

Sir Hugh Cairns, Nuffield professor of surgery in the University of Oxford, has left for a three months' visit to Australia and New Zealand as the first Arthur Sims travelling professor of the college. He will deliver lectures, make contact with medical scientists, and take part in research and postgraduate teaching. Later he is also to visit the principal medical centres of South Africa.

Colonial Office

Dr. R. S. F. Hennessey has been appointed an assistant medical adviser at the Colonial Office.

Dr. Hennessey, who is 42, graduated M.B. at Dublin in 1927, and later studied at the London School of Hygiene and Tropical Medicine, taking the DIPL. BACT. in 1932 and the D.T.M. & H. in 1930. In 1932 he also obtained his M.D. and in 1935 he became M.R.C.P.I. He was appointed to the Colonial Medical Service in 1929, and joined the Uganda laboratory service as a pathologist in that year. In 1944 he was transferred to Palestine as deputy director in charge of the Government medical laboratories, and later became deputy director of the Palestine department of health. While in Uganda, Dr. Hennessey was lecturer in pathology at Makerere College medical school. His published work on tropical pathology includes papers on keratomalacia in liver disease and on leucocyte output and vitamin intake. He was an associate editor of the *East African Medical Journal*.

MEDICAL

Vitamin Therapy—its uses and limitations

DIET IN PREGNANCY

Reports indicating the effect of improved nutrition on the figures of maternal mortality and morbidity, as well as of infant and neo-natal mortality, have focussed attention on the importance of diet in pregnancy.

The lowering of the death rate of infants under one year from 50.6 per thousand in 1939 to 45.4 in 1944 was no doubt mainly due to the priority supply of essential nutrients to expectant mothers, since during this time environmental conditions were in many cases exerting an adverse influence.

It had already been shown in a survey involving 5,000 women in 10 London hospitals that the incidence of toxæmia was significantly lower among women receiving supplements of essential vitamins and minerals. Moreover, work in the U.S.A. had demonstrated that the average birth weight of children whose mothers were on a poor diet was over 2 lbs. less than that of the children of well-fed mothers.

Improvement could be expected if all pregnant women took advantage of the priority supplies allowed them. But to *ensure* an adequate intake of *all essential nutrients* Pregnavite should be prescribed.

PREGNAVITE

A *single* supplement for safer pregnancy

The recommended daily dose provides:

vitamin A	2,000 i.u.	vitamin E	1 mg.	iodine manganese copper	not less than 10 p.p.m. each
vitamin D	300 i u.	nicotinamide	25 mg		
vitamin B_1	0.6 mg.	calcium	160 mg.		
vitamin C	20 mg	iron	68 mg.

MEDICAL

An Effective Analgesic

WHILE modern chemical research has evolved many and diverse analgesics, the popularity of acetylsalicylic acid and its reputation for effectiveness remain. Nevertheless, some physicians have hesitated to employ it owing to its tendency, in certain conditions, to irritate the stomach.

In 'Alasil,' however, the desirable therapeutic effects of acetylsalicylic acid are maintained without the tendency to irritation by combining the acid with Dibasic Calcium Phosphate and 'Alocol' (Colloidal Aluminium Hydroxide) —an effective gastric sedative and antacid. Thus 'Alasil' helps to solve the problem of administering acetylsalicylic acid in an effective form, even to patients with sensitive stomachs.

The advantages of 'Alasil' have been well proved in practice. Experience shows that it can be prescribed with safety to patients of all ages.

AVOID-
your Patient's Cold...

A pleasant way of preventing infection from patients suffering from colds is the timely application of 'Endrine.' A few drops sniffed up each nostril will avoid the discomforts of nasal congestion and the chance that you yourself will infect your patients. 'Endrine,' with its carefully selected ingredients and well-balanced formula, acts as a mild astringent, and by reducing nasal congestion, promotes sinus drainage and improves breathing.

For Normal Infant Feeding

BIRTH TO NINE MONTHS

Humanised Trufood

PROTEIN

The ratio of casein to lactalbumen is adjusted to provide a total amino acid content which closely resembles that of human milk.

FAT

The presentation of the fat in the form of a finely diffused emulsion reduces the likelihood of fat intolerance.

CARBOHYDRATE

Lactose is the only carbohydrate present and constitutes 50/55 % of the total solids.

1 OZ. OF POWDER CONTAINS:

600 I.U. Vitamin “A”	150 mg. Calcium
320 I.U. Vitamin “D”	150 mg. Phosphorus
0.3 mg. Iron	

HUMANISED TRUFOOD. An Infant food scientifically balanced to the standard of Human Milk.

✱ A successful treatment for CHILBLAINS

In 1942 research was carried out to try determine what effect various kinds of ork and conditions had on the prevalence of blains. Over 3,000 women between the ages 20-40 were questioned.

While therapeutics were no particular of the investigation, one special ointment given a trial in various parts of the country. dical Officers reported that, under the uence of this ointment, pain from chilblains alleviated and rapid healing was general. e of the reports said that the ointment was best remedy yet produced (see Winner and per Willis, 'Lancet' Nov. 9th, 1946).

At this time of the year many of your ents will doubtless complain of pain, tation, and sometimes misery caused by blains, and the Perivale Laboratories there- have prepared Perivale Chilblain Ointment de according to the formula of that used in 1942 research. It consists of: Phenol 1%, phor 6%, Balsam of Peru 2%, Paraffin and oline base to 100 parts by weight. It is sed that the affected parts be immersed in water at bedtime, dried carefully and the tment applied, or that the ointment be rubbed ght and morning.

IVALE CHILBLAIN OINTMENT

PHILIPS D.X.

A High Powered
Four Valve Unit

The fact that many hospitals are already using the Philips D.X.4 Diagnostic X-ray Unit bears witness to its success and is a recommendation in itself.

An important feature of the D.X.4 is the new Quantic Control. This allows for a combination of Kilovoltage, mA and time up to and including the optimum but *not more*. Also the operator is not required to compare his selected radiographic conditions with the tube rating chart. This is done automatically by the apparatus itself.

British-made throughout, the D.X.4 is a first-class operational unit, the pride of any hospital's X-ray Department. More information will be gladly supplied on request.

Indifference to food . . .

is an indication for

ELIXIR 'VIRVINA'

a palatable elixir of the vitamin B complex with glycerophosphates.

Each fluid ounce of Elixir 'Virvina' contains:

Thiamine hydrochloride (Vitamin B_1)	4.0 mg. (1332 I.U.)
Riboflavin (Vitamin B_2 or G)	2.0 mg.
Pyridoxine hydrochloride (Vitamin B_6)	0.1 mg.
Nicotinic Acid Amide	30.0 mg.
Calcium, Sodium, Potassium and Manganese glycerophosphates (total)	6.625 grains

Elixir 'Virvina' stimulates the appetite, improves digestive functions and corrects deficiencies of the vitamin B complex. It is unusually palatable and may be administered regularly as a dietary supplement especially during childhood, pregnancy, convalescence and old age, when the body's requirements for minerals and for the factors of the vitamin B complex are above normal.

Elixir 'Virvina' is supplied in 4 oz., 16 oz. and 80 oz. bottles. Informative literature will be supplied on request.

MICRO-CRYSTALLINE HORMONES

Micryston Oestrone x 175

OESTRONE

and

TESTOSTERONE

FOR

SUSTAINED ACTION

Unlike hormone solutions, suspensions of hormone crystals are absorbed slowly and their effect is thereby enhanced and protracted. Micryston Oestrone is thus rational in oestrogenic deficiency and Micryston Testosterone in testicular deficiencies. As, in many cases, one weekly injection produces a sustained flow of hormone, a great economy of material and effort is attained
